BELLE NOTE 1486

2

Measurement of the decay

3

$B^+ \rightarrow K^+ K^- \ell^+ \nu_\ell$ with B2BII

4

Matic Lubej

5

Ljubljana, 2018

Changelog

- 4. May: First submission of the note.
- 16. May: Added ROE validation section.
- 7. July: update of whole BNOTE, B2BII chapter, finishing control fits.
- 19. August:
 - More details on the fit process and background splitting.
 - Adding sources of systematics
 - Ready for box opening

Chapter 1

Introduction

Particle physics is an established branch of physics with a rich history in theory and experiments ever since the beginning of the 20th century. So far the experimental and theoretical research have shown us hand in hand that the universe consists of particles and force carriers. Particles of matter, or elementary particles, are divided into two groups, quarks and leptons. The quarks that we know today are called u (up), d (down), s (strange), c (charm), b (bottom) and t (top). Leptons are further split into two groups; charged leptons e (electron), μ (muon), τ (tau lepton) and their corresponding neutrinos ν_e (electron neutrino), ν_μ (muon neutrino), ν_τ (tau neutrino). Particles of force are known as gauge bosons and they are γ (photon), g (gluon), W^\pm (charged weak bosons) and Z^0 (neutral weak boson). Theoretical calculations also predicted the recently discovered Higgs boson (H), which is responsible for the mass of all particles. Some of the particles above also have a mirrored version of themselves, called antiparticles, which exhibit somewhat different properties as their un-mirrored versions.

Combinations of quarks such as $q_1 q_2 q_3$ (hadrons) or $q_1 \bar{q}_2$ (mesons) can make up heavier particles that we see today. Such particles are protons and neutrons, but also heavier particles which can be produced in processes involving very high energies. Such heavy particles are unstable and decay into lighter ones via forces of nature. Together with the elementary particles and force carriers, three out of four of these forces are joined in a theoretical model called the Standard Model (SM), which is shown in Figure 1.1. They are the electromagnetic, weak nuclear and strong nuclear force. Gravity is not included in the current version of the Standard Model due to mathematical singularities associated with the point-like nature of elementary particles. We can afford to ignore it due to its weakly interacting nature. Researching such processes in large experiments enables us to study the mechanism of how elementary particles interact. By doing so we are able to learn the secrets of the universe and how it all began.

Figure 1.1: A schematic of the Standard Model.

This analysis revolves around decays of the so-called B mesons, which are particles that consist of a b quark and a light \bar{u} or \bar{d} quark (or vice-versa). One of the most surprising features of the universe that can be studied with decays of B mesons is the CP symmetry violation (\mathcal{CP}). CP symmetry is a combination of the C symmetry (charge conjugation) and the P symmetry (spatial inversion). It states that there is no reason why processes of particles and mirrored processes of antiparticles would be different. Today we know that this does not hold for all cases and we, in fact, find processes which violate this postulate. We also know that \mathcal{CP} is very closely related to the weak nuclear force. Here lies our motivation for studying decays of B mesons, since they exhibit a rich spectrum of decays which proceed via the weak nuclear force.

One of the most important properties of the weak nuclear force is that it can change the flavor of particles. Flavor is a quantum number which is conserved for each type of quark, so changing a flavor of a quark means changing the quark itself. Such processes are forbidden for the electromagnetic and the strong nuclear force, but not for the weak one. All the information about quark transitions and transition probabilities can be merged into a form of a complex matrix called the Cabibbo-Kobayashi-Maskawa (CKM) matrix [1, 2]

$$V_{CKM} = \begin{bmatrix} V_{ud} & V_{us} & V_{ub} \\ V_{cd} & V_{cs} & V_{cb} \\ V_{td} & V_{ts} & V_{tb} \end{bmatrix}. \quad (1.1)$$

The CKM matrix is a unitary matrix and has only four free parameters which are not described by theory. Its unitarity provides us with several mathematical identities, out of which the most famous one is

$$V_{ud}V_{ub}^* + V_{cd}V_{cb}^* + V_{td}V_{tb}^* = 0. \quad (1.2)$$

It can be represented by a triangle in the complex plane, called the unitarity triangle, shown in Figure 1.2. The sides and the angles of the unitarity triangle are

160 closely connected to the free parameters of the CKM matrix. It is important to
 161 mention that all experimental measurements depend only on these four parameters,
 162 so it is possible to determine them by measuring the angles and sides of the unitarity
 163 triangle. This way the unitarity triangle offers us a unique way to test the consistency
 164 of the SM. The ultimate goal is to then join all such measurements and overconstrain
 165 the unitarity triangle to check if all the sides meet. By improving such measurements
 166 one can check whether the SM is consistent, or if there are some contributing physics
 167 processes that we do not yet understand. Such processes are commonly referred to
 168 as "new physics" (NP). The measurements of the sides and angles of the triangle
 169 are done by using different decays out of which a large portion are B meson decays.
 170 Here lies another motivation for using B mesons in the analysis.

Figure 1.2: The unitarity triangle with λ , η , ρ and A (not shown) as free parameters of the CKM matrix, shown in the Wolfenstein parametrization [3].

171 In this analysis, we focus on the V_{ub} CKM matrix element, which corresponds to
 172 $b \rightarrow u$ quark transitions. It has the smallest absolute value of all the CKM matrix
 173 elements and the largest error, so it offers the most room for improvement. Such
 174 quark transitions are present in charmless semileptonic B meson decays of the form

$$B^+ \rightarrow X_u^0 \ell^+ \nu_\ell, \quad (1.3)$$

175 where X_u^0 represents a charmless hadron with a u quark and ℓ is one of the charged
 176 leptons e , μ or τ . Measuring the decay rate of the B meson in such decays paves the
 177 way for the CKM matrix element determination. Decay rates are directly connected
 178 to the V_{ub} element as

$$d\Gamma \propto G_F^2 |V_{ub}|^2 |L^\mu \langle X_u | \bar{u} \gamma_\mu \frac{1}{2} (1 - \gamma_5) b | B \rangle|^2, \quad (1.4)$$

179 where Γ is the decay width, G_F is the Fermi coupling constant, L^μ is the leptonic
 180 current and the expression in the Dirac brackets is the hadronic current. The factor
 181 $|V_{ub}|^2$ represents the probability for the $b \rightarrow u$ quark transition. Measurement
 182 of the V_{ub} CKM matrix element can be performed in two possible ways, with the
 183 exclusive or the inclusive method, both of which are described below. Both methods
 184 require different experimental and theoretical techniques, so they provide largely
 185 independent determinations of $|V_{ub}|$. Currently, both methods also have comparable
 186 accuracies.

187 In the exclusive method, one studies the decays of B mesons to a specific charmless
 188 hadronic final state, such as $B \rightarrow \pi \ell \nu$. Clean determination of the V_{ub} is possible due

to precise experimental measurements along with reliable theoretical calculations. However, theoretical calculations are more challenging for decays to a specific final state, since hadronization of quarks has to be taken into account. There are also two main experimental challenges in this method. One has to reduce the abundant background from $B \rightarrow X_c \ell \nu$ processes since the $b \rightarrow c$ quark transition is much more common. The second experimental challenge is to separate the B meson decay with the specific charmless hadronic final state from other $B \rightarrow X_u \ell \nu$ decays since it roughly populates the same regions of the phase-space as the signal decay.

In the inclusive method, one studies the decays of B mesons to any charmless hadronic final state $B \rightarrow X_u \ell \nu$. In this case, the total decay rate for $b \rightarrow u \ell \nu$ can be calculated accurately since hadronization does not have to be taken into account. The greater challenge with this method is again the experimental measurement of the total decay rate due to the $B \rightarrow X_c \ell \nu$ background. Experimental sensitivity to V_{ub} is highest where $B \rightarrow X_c \ell \nu$ decays are less dominant. Theory and experiment have to compromise and limit the V_{ub} determination to a region where the signal-to-background ratio is good. Theoretical calculations take this into account by reliably calculating the partial decay rate $\Delta\Gamma$, which is more challenging than the total decay rate. One possible and often used approach to reduce $b \rightarrow c$ background is to reject all events with K particles, or kaons, present in the final particle selection. The procedure is called a K -veto. Kaons consist of an s quark, which is mainly produced in $c \rightarrow s$ transitions. This means that if a kaon is found in the event, it is very likely that it originates from a particle with a c quark, indicating the $b \rightarrow c$ process.

If V_{ub} is determined with both these methods, the values can be compared. It turns out that consistency between these two results is only marginal, where the difference is at a level of 3σ . The current world averages [4] of the exclusive (from $B^0 \rightarrow \pi^- \ell^+ \nu$) and inclusive (GGOU collab. [5]) are

$$|V_{ub}|_{\text{excl.}} = (3.65 \pm 0.09 \pm 0.11) \times 10^{-3}, \quad (1.5)$$

$$|V_{ub}|_{\text{incl.}}^{\text{GGOU}} = (4.52 \pm 0.15 \pm_{-0.14}^{+0.11}) \times 10^{-3}, \quad (1.6)$$

where the first and the second errors are the experimental and the theoretical error, respectively. We see that inclusive measurements prefer higher values than exclusive ones. This is known as the V_{ub} puzzle. It is necessary to make further research as to why this difference occurs. The reason could be an unknown experimental or theoretical error, or it is even possible that some NP contributions occur. This analysis will focus on a possible reason that could be hidden in the selection mentioned before. By performing a K -veto, one discards all events with kaons in the final state in order to suppress $b \rightarrow c$ contributions. In this analysis, we focus on the charged $B \rightarrow KK \ell \nu$ decay, which is very similar to the $B \rightarrow \pi \ell \nu$, except for a production of an $s\bar{s}$ quark pair, which then combines with final state quarks to form kaons, as shown in Figure 1.3. In this case, we have kaons in the final state where the B meson decayed via a $b \rightarrow u$ process. Such decays were discarded in previous V_{ub} determinations with the inclusive method, but in principle, they contribute to the result and should be taken into account. The results of this analysis should help us make a step closer to solving the V_{ub} puzzle.

Figure 1.3: Feynman diagrams for the $B^+ \rightarrow \pi^0 \ell^+ \nu_\ell$ decay (left) and the $B^+ \rightarrow K^- K^+ \ell^+ \nu_\ell$ decay (right).

227 Specifically, we will be focusing on decays of the charged B mesons of the form
 228 $B^+ \rightarrow K^+ K^- \ell^+ \nu$, since it includes two charged kaons, as opposed to the case of the
 229 neutral B meson decay. The reason for this is a simpler decay chain and a higher
 230 reconstruction efficiency. All further occurrences of $B \rightarrow K K \ell \nu$ automatically imply
 231 decays of the form $B^+ \rightarrow K^+ K^- \ell^+ \nu$ and its charge conjugated counterpart.

Chapter 2

Data and Monte-Carlo Samples

The Belle detector acquired a dataset of about $L_0 \approx 710 \text{ fb}^{-1}$ of integrated luminosity in its lifetime at the $\Upsilon(4S)$ energy of 10.58 GeV, which corresponds to about $771 \times 10^6 B\bar{B}$ meson pairs. Additionally, several streams of Monte-Carlo (MC) samples were produced, where each stream of MC corresponds to the same amount of data that was taken with the detector. The main focus of this and other similar analyses is to study a rare signal decay, which means that the amount of such decays in the existing MC is not abundant enough. In such cases, it is a common practice to produce specific samples of signal MC, where the abundance of signal decays is much larger, enabling us to study its properties in greater detail.

The following samples were used in this analysis

- data

- Belle on-resonance dataset of about L_0 integrated luminosity, measured at $\Upsilon(4S)$ resonance energy,
- Belle off-resonance dataset of about $1/10 \times L_0$ integrated luminosity, measured at 60 MeV below $\Upsilon(4S)$ resonance energy,

- signal MC, corresponding to about $400 \times L_0$,

- other MC

- generic on-resonance, 10 streams of B^+B^- and $B^0\bar{B}^0$ (denoted as **charged** and **mixed**) and 6 streams of $q\bar{q}$ produced at $\Upsilon(4S)$ resonance energy, where each stream corresponds to L_0 ,
- generic off-resonance, 6 streams of $q\bar{q}$ produced at 60 MeV below $\Upsilon(4S)$ resonance energy, where each stream corresponds to $1/10 \times L_0$,
- $B \rightarrow X_u \ell \nu$ (denoted as **ulnu**), not included in previous MC samples, equal to an amount of $20 \times L_0$,
- other rare B meson decays (denoted as **rare**), not included in previous MC samples, equal to an amount of $50 \times L_0$.

2.1 Signal MC Production

The signal MC sample of $B^+ \rightarrow K^+ K^- \ell \nu_\ell$ and the charge conjugated B^- decays was produced using the `mcproduzh` [6, 7] package for producing Belle MC. The package accepts a decay file, which describes the decays to be generated. The decay file used for signal MC generation was the same as for the **ulnu** sample since it includes the decays of interest. An additional skim was applied in order to select

only events of interest with at least 2 kaons and a light lepton, all coming from the same particle. This decreases the CPU consumption during the detector simulation and reconstruction.

The relevant processes which contribute to our signal decay are

- $B^+ \rightarrow a_{00}\ell^+\nu_\ell$,
- $B^+ \rightarrow a_{20}\ell^+\nu_\ell$,
- $B^+ \rightarrow f_2\ell^+\nu_\ell$,
- $B^+ \rightarrow f_0\ell^+\nu_\ell$,
- $B^+ \rightarrow X_u^0\ell^+\nu_\ell$,

where a_{00} , a_{20} , f_2 and f_0 are light unflavored states which include further decays into a K^+K^- pair, and X_u^0 represents a generic $u\bar{u}$ quark pair, which further hadronizes based on the PYTHIA quark hadronization model [8]. Figure 2.1 shows the invariant mass of the KK pair from various contributions of the MC generator. The light unflavored states have small contributions with resonant structures, while KK pairs from the X_u^0 state are more frequent and follow a wider and smoother distribution.

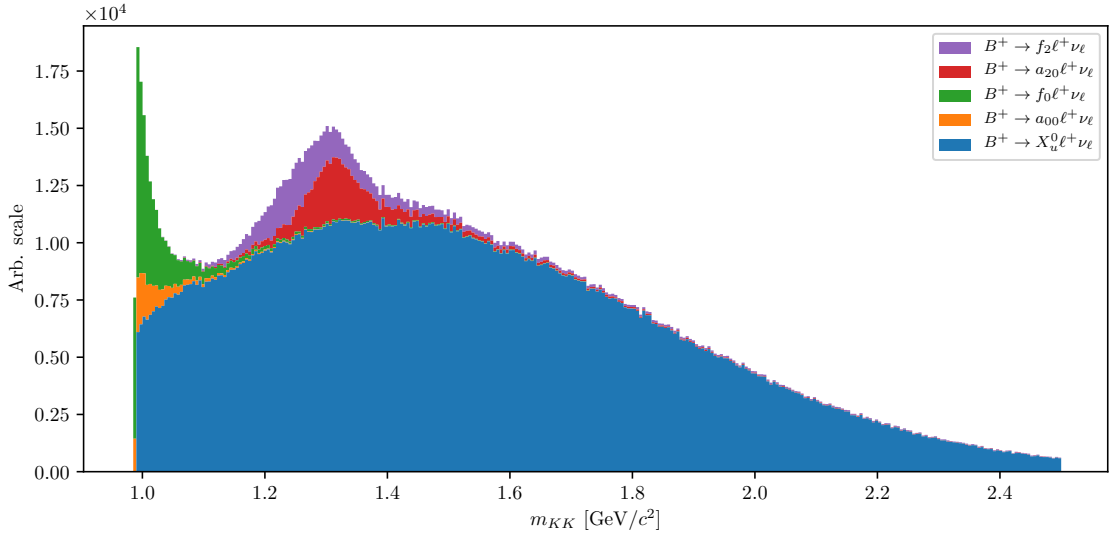

Figure 2.1: Invariant mass of the KK pair from various contributions of the MC generator. The light unflavored states have small contributions with resonant structures, while KK pairs from the X_u^0 state are more frequent and follow a wider and smoother distribution.

The produced signal MC sample contains decays of the form $B \rightarrow KK\ell\nu$ as well as $B \rightarrow KKX\ell\nu$, where X can be any hadron as long as it satisfies all the selection rules of the decay. It is possible to calculate the MC branching ratios for each channel by making combinations of the particles directly from the generator. Table 2.1 shows some of the most prominent channels, which are similar to our signal decay, as well as their relative fraction. It is clear that our signal decay is the most abundant one, with a relative contribution of about 28 %, while other

channels contribute only up to about 8 % or less. Additionally, our signal decay is the cleanest, while other decays include neutral particles like π^0 , which are harder to reconstruct and suffer from a decrease in efficiency due to reconstruction effects.

Channel	Ratio [%]	Channel	Ratio [%]
K^+K^-	28.14	$K^+K^-\rho^0$	1.93
$K^+K^-\pi^0$	8.94	$K^+\bar{K}^0\rho^-$	1.84
$K^+\bar{K}^0\pi^-$	8.71	$K^0K^-\rho^+$	1.83
$K^0K^-\pi^+$	8.70	$K^0\bar{K}^0\rho^0$	0.00
$K^+K^-\pi^+\pi^-$	4.15	$K^+K^-\pi^0\pi^0$	0.86
$K^0\bar{K}^0$	3.32	$K^+K^-\pi^+\rho^-$	0.69
$K^0\bar{K}^0\pi^0$	3.26	$K^+K^-\rho^+\pi^-$	0.68
$K\bar{K}$ pair with η	7.08		
$K\bar{K}$ pair with ω	5.33		
Other	14.53		

Table 2.1: Relative branching ratios of $B \rightarrow KKX\ell\nu$ decays by channel.

We generate about 1.3×10^9 events of the form $B \rightarrow X_u\ell\nu$, which corresponds to an integrated luminosity of about $L = 400 \times L_0$, where this value was obtained by normalizing the signal MC to the amount of signal in the $B \rightarrow X_u\ell\nu$ MC sample. This amounts to a total of about 9.37×10^6 generated signal events, and to a branching ratio

$$\mathcal{B}(B^+ \rightarrow K^+K^-\ell^+\nu_\ell)_{MC} = 1.53 \times 10^{-5}, \quad (2.1)$$

where ℓ is e or μ . During analysis, the abundant signal MC sample is scaled down to correspond to the amount of data taken with the Belle detector.

2.2 Control Decay

In this analysis, we are also able to define another B meson decay which occupies almost the same phase space as our signal decay. This process can be used for the monitoring of our analysis steps, which are applied to both measured and simulated data. Any kind of difference between the two might indicate our procedure to be fine-tuned to simulated data, or some other similar problem.

We define a control decay of the form

$$B^+ \rightarrow \bar{D}^0\ell^+\nu, \quad D^0 \rightarrow K^+K^-,$$

which is much more abundant and, most importantly, easy to suppress since it only populates a very narrow region in the kaon invariant mass spectrum. Due to no extra particles in the D^0 decay, the kaon invariant mass is equal to $m_{KK} \approx m_{D^0}$ up to very good precision. By excluding this narrow region we discard the majority of the control candidates while discarding only a small amount of the signal candidates. A more quantitative description of suppressing control and other background candidates is written in chapter 6.

Chapter 3

Belle to Belle II Format Conversion

3.1 Conversion Procedure

The Belle experiment finished its data-taking run of 10 years at the end of 2010 after collecting a dataset of about 1 ab^{-1} . That year the Belle detector was shut down and the Belle II experiment has started in its place. While the focus moved to the construction of the Belle II detector and the development of the Belle II Analysis Framework (BASF2), Belle analyses are still on-going and Belle data is still being used today. BASF2 software with its modular structure has a more intuitive approach to performing analyses, however, since it was rewritten completely from scratch, it was designed for the incoming Belle II data and therefore out-of-the-box usage of Belle data is outside of its scope.

In the Belle II Collaboration, a task force was created in order to convert Belle data into Belle II format (B2BII). The B2BII package was developed as a part of BASF2 in order to convert data and MC of the Belle experiment and make it available within BASF2. In addition to the convenience of Belle data being processed in the more intuitive and advanced BASF2 framework, B2BII allows for estimation and validation of performances of various advanced algorithms being developed for Belle II. The conversion itself, however, is considered non-trivial. Although the conversion of the raw detector data would be possible, the reconstruction algorithms of BASF2 are optimized for Belle II and cannot be effectively applied to Belle data. To bypass this problem, reconstructed objects from **PANTHER** tables, a custom solution of the Belle collaboration based on C/C++ and Fortran, are mapped to their corresponding representations in BASF2. In this analysis, we use the developed converter package in order to analyze Belle data with the Belle II software.

The conversion in the B2BII package is divided into three BASF2 modules. The first module opens the Belle input files and reads the events into memory in the form of **PANTHER** tables. This module consists predominantly of reused BASF code. The second module applies various calibration factors, such as experiment- and run-dependent factors, to the beam energy, particle identification information, error matrices of the fitted tracks, etc. The module also applies some low-level cuts to reproduce removing background events as done within BASF. The actual conversion and the mapping of reconstructed objects are done in the last module. For more information see [9].

3.2 Validation

In order to make sure the conversion was successful and without errors, a thorough validation should be performed. This is done by comparing histograms of all physical quantities of the reconstructed objects on simulated and recorded events, processed with BASF and BASF2.

Our signal decay mode consists of three charged tracks, track conversion should perform flawlessly. Additionally, energy measurement is also very important in our untagged analysis in order to successfully determine the missing 4-momentum in the event, which is why we also need a correct conversion of the ECL clusters for photons and π^0 particles. Figures 3.1 to 3.3 show the basic physical properties of converted tracks, photons and π^0 particles, obtained with BASF and BASF2, and their difference, which is (up to numerical precision) equal to 0. The plots indicate that the conversion is successful in all aspects and we can proceed with the analysis in the framework of BASF2.

Figure 3.1: Some of the more important physical properties of tracks for Belle and Belle II in the conversion process. The histograms seem to overlap and the conversion is assumed to be successful.

Figure 3.2: Some of the more important physical properties of photons for Belle and Belle II in the conversion process. The histograms seem to overlap and the conversion is assumed to be successful.

Figure 3.3: Some of the more important physical properties of π^0 particles for Belle and Belle II in the conversion process. The histograms seem to overlap and the conversion is assumed to be successful.

Chapter 4

Event Reconstruction

In this chapter the procedure for event reconstruction of the B meson decay $B \rightarrow KK\ell\nu$ is shown, starting with final state particle selection and then combining them to obtain B meson candidates.

4.1 Final State Particles Selection

Since the neutrino escapes detection, we can only reconstruct the charged tracks in the decay, which are the two charged kaons (K) and the light lepton, which is the electron (e) or muon (μ). These are some of the particles which are commonly referred to as final state particles (FSP). Final state particles have a long lifetime and are usually the particles that we detect when they interact with the material in the detector.

It is important to limit our selection of FSP particles in order to cut down the number of particle combinations, and consequentially computation time and file sizes.

At this point in the analysis, we do not apply any intelligent cuts yet, which results in a large number of available particles and their combinations. In order to minimize this effect, we perform this part of the study on a smaller subset of the available generic MC, experiment no. 23 and 31, which correspond to an integrated luminosity of 6.273 fb^{-1} and 17.725 fb^{-1} , respectively. We chose these two experiments to get closer to the appropriate ratio of SVD1 and SVD2 data in the full Belle MC.

Leptons

Figures 4.1 and 4.2 show the impact parameters d_0 and z_0 , the momentum in $\Upsilon(4S)$ center-of-mass system (CMS), and the PID information for true and fake electrons and muons from any source, where an extra category for true electrons/muons from the signal B meson decay is shown. The difference between the true leptons from any source and those from signal decays is due to the distinct kinematics of the parent's decay to the electron.

Figure 4.1: Normalized properties of true (blue), fake (red) electrons from any source, and true electrons from signal B candidates (green).

Figure 4.2: Normalized properties of true (blue), fake (red) muons from any source, and true muons from signal B candidates (green).

Based on these distributions, we can define a set of cuts

- $|d_0| < 0.1$ cm,
- $|z_0| < 1.5$ cm,
- $p_{CMS} \in [0.4, 2.6]$ GeV/ c for electrons,
- $p_{CMS} \in [0.6, 2.6]$ GeV/ c for muons.

After this selection we can determine the optimal PID cuts for electrons and muons, where we optimize the selection by maximizing the standard definition of *figure of merit* (FOM), defined in Eq. (4.1)

$$\text{FOM} = \sqrt{\mathcal{E}\mathcal{P}} \propto \frac{S}{\sqrt{S+B}}, \quad (4.1)$$

where the argument in the square root is the product of the efficiency (\mathcal{E}) and the purity (\mathcal{P}) function. The definitions of signal (S) and background (B) are somewhat fluid throughout the analysis and need to be defined for each FOM separately. In this section we define two representations of S and B . In FOM₁ the signal S represents correctly reconstructed final state particles, while in FOM₂ the signal S represents correctly reconstructed final state particles which also come from a correctly reconstructed B meson candidate. In both cases B represents all other particle candidates which do not satisfy the conditions of S .

The FOM plots are shown in Figures 4.3 and 4.4. The cut values are based on PID cuts used for PID efficiency calibration. The optimal value for the PID cuts is equal to the largest available value, regardless of the leptons coming from signal decays or not. The optimized PID cuts for leptons are

- e prob. > 0.9 for electrons,
- μ prob. > 0.97 for muons.

Figure 4.3: FOM optimizations of the PID probability cuts for true electrons (left) and true electrons from signal B candidates (right).

Figure 4.4: FOM optimizations of the PID probability cuts for true muons (left) and true muons from signal B candidates (right).

410 **Kaons**

411 We repeat the procedure for both kaons. Figure 4.5 shows the impact parameters
 412 d_0 and z_0 , the momentum in $\Upsilon(4S)$ center-of-mass system (CMS), and the PID
 413 information for true and fake kaons, where an extra category for true kaons from
 414 the signal decay is shown.

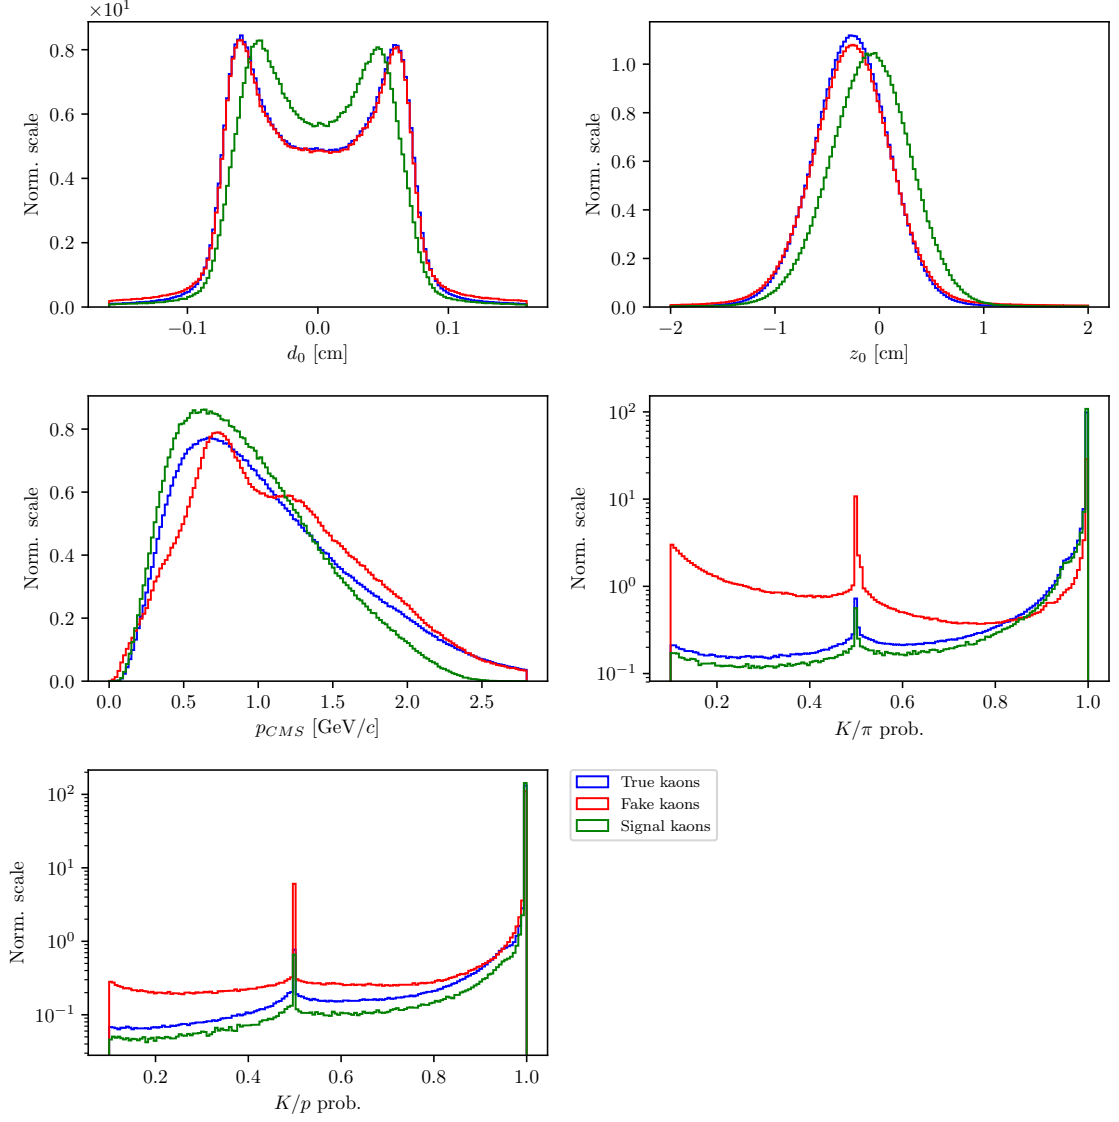

Figure 4.5: Normalized properties of true (blue), fake (red) and true kaons (green) from signal B candidates.

We define the kaon cuts in the same manner as in the case for leptons

- $|d_0| < 0.15$ cm,
- $|z_0| < 1.5$ cm,
- $p_{CMS} \in [0, 2.5]$ GeV/ c .

The PID optimization, in this case, is taken in two steps. First, we optimize the cut on K/π , and after that the K/p separation probability. Figure 4.6 shows the optimization procedure for PID cuts on kaon candidates.

Figure 4.6: FOM optimizations of the PID probability cuts for true kaons (top) and true kaons from signal B candidates (bottom). The plots on the left show the optimization of the first step for the K/π probability cut, and the plot on the right the K/p probability cut.

The optimized PID cuts for kaons are

- $K/\pi > 0.6$,
- $K/p > 0.1$.

4.2 Pre-selection of First B Meson Candidates

In this section, we use the charged particle candidates from the previous section to make particle combinations, which correspond to B meson candidates. When a B meson candidate is selected, additional features can be calculated and used for background rejection. Since we are still performing this part of the study on

430 a smaller subset of the full available MC sample, we will perform under-optimized
 431 cuts based on the FOM optimization in order to optimize them later on the full
 432 Belle MC sample.

Since the missing neutrino escapes detection, we reconstruct the B mesons in the following two channels

$$\begin{aligned} B^+ &\rightarrow K^+ K^- e^+, \\ B^+ &\rightarrow K^+ K^- \mu^+, \end{aligned}$$

433 and similarly for B^- . When an arbitrary combination is obtained, we perform a
 434 vertex fit of the three tracks in order to discard combinations with a low probability
 435 of tracks coming from the same point. B mesons have a relatively long lifetime and
 436 decay along the z axis of the detector in the direction of the boost, so the vertex fit
 437 is enforced with an IPTUBE constraint, which constrains the vertex to an elongated
 438 ellipsoid along beam direction. We demand that the fit converged and apply a cut on
 439 the minimal fit probability. The fit probability for signal and background B meson
 440 candidates is shown in Figure 4.7 (left). We perform a FOM cut optimization of
 441 this variable, which is shown in Figure 4.7 (right) for the subset of the Belle MC
 442 sample. In this and in the following cases, the definition of S from Eq. (4.1) are
 443 correctly reconstructed B meson candidates with a missing neutrino which are not
 444 coming from a $b \rightarrow c$ transition.

Figure 4.7: Normalized vertex fit probability distribution for signal and background B meson candidates in logarithmic scale(left) and FOM optimization of the vertex fit probability (right) for the subset of the full Belle MC sample.

445 The chosen pre-cut on the fit probability is

- 446 • $P(\chi^2, NDF) > 1.0 \times 10^{-3}$.

447 With the neutrino being the only missing particle on the reconstructed side, it
 448 is possible to determine the angle between the direction of the reconstructed B
 449 (denoted as $Y \rightarrow KK\ell$) and the nominal B , as

$$p_\nu = p_B - p_Y, \quad (4.2)$$

$$p_\nu^2 = m_\nu^2 = m_B^2 + m_Y^2 - 2E_BE_Y + 2\vec{p}_B \cdot \vec{p}_Y \approx 0, \quad (4.3)$$

$$\cos(\theta_{BY}) = \frac{2E_BE_Y - m_B^2 - m_Y^2}{2|\vec{p}_B||\vec{p}_Y|}, \quad (4.4)$$

where p denotes a scalar, \vec{p} a vector, and p a 4-vector. All the energy and momenta above are calculated in the CMS frame. The mass of the neutrino is equal to 0 to a very good precision, so we use it in Eq. (4.3). In addition, we substitute the unknown energy and momentum magnitude, E_B and $|\vec{p}_B|$, of the B meson in Eq. (4.4), with quantities from the well known initial conditions

$$E_B = E_{CMS}/2, \quad (4.5)$$

$$|\vec{p}_B| = p_B = \sqrt{E_B^2 - m_B^2}, \quad (4.6)$$

where E_{CMS} is the total energy of the e^+e^- collision in the CMS frame and m_B is the nominal mass of the B meson. This improves the resolution of $\cos(\theta_{BY})$, which leads to better signal-to-background discrimination.

For the correctly reconstructed candidates, this variable lies in the $[-1,1]$ region, though only to a certain precision, due to the finite detector resolution. Background candidates, however, populate also the non-physical regions, as shown in Figure 4.8 (left).

Figure 4.8: Normalized $\cos\theta_{BY}$ distribution for signal and background B meson candidates (left) and FOM optimization of the $\cos\theta_{BY}$ variable (right) for the subset of the full Belle MC.

We again impose an under-optimized cut on this variable from Figure 4.8 (right) to discard a large amount of background on this subset of the full Belle MC

$$\bullet \quad |\cos(\theta_{BY})| < 1.20.$$

4.3 Loose Neutrino Reconstruction

The signal-side neutrino escapes detection, so we cannot directly determine its four-momentum. However, due to the detectors geometry, which almost completely covers the full solid angle, and due to well known initial conditions of the $\Upsilon(4S)$ meson, it is possible to determine the kinematics of the missing neutrino via indirectly reconstructing the companion B meson by summing up the four-momenta of all the FSP particles in the event which were not used in the reconstruction of the signal side B meson. This is known as the *untagged* method since we are not using any kind of tagging method to reconstruct the companion B meson. The particles used in the indirect companion B meson reconstruction are also said to belong to the *rest of the event* (ROE).

Due to the beam background in the detector, material interactions, or other processes, random tracks and clusters enter our event and get reconstructed as part of the physics process we want to study. These tracks and clusters are not interesting and further spoil the data we measure. In order to remedy this, we perform an extensive clean-up of the tracks and clusters in the ROE side before calculating the four-momentum of the missing part of the event. Here we see the motivation for the ROE clean-up since our signal candidate reconstruction depends on tracks and clusters in the ROE side. The clean-up procedure is performed separately on tracks and clusters and uses multiple steps with multivariate analysis (MVA) algorithms in order to separate good tracks and clusters from the bad ones, which populate the ROE. Then, for each ROE object, a ROE mask is created for tracks and clusters, which narrates the use of this object in the final calculations of the ROE four-momentum. From this point on we assume the ROE to be efficiently cleansed of extra tracks and clusters. A more detailed description of the ROE clean-up can be found in Chapter 5.

The total missing four-momentum in the event can be determined as

$$p_{miss} = p_{\Upsilon(4S)} - \sum_i^{\text{Event}} (E_i, \vec{p}_i), \quad (4.7)$$

$$p_{miss} = p_{\Upsilon(4S)} - \left(p_Y - \sum_i^{\text{Rest of event}} (E_i, \vec{p}_i) \right), \quad (4.8)$$

where the summation runs over all charged and neutral particles in the defined set with

$$p_i^{\text{neutral}} = (p_i, \vec{p}_i) \quad \text{and} \quad p_i^{\text{charged}} = \left(\sqrt{m_i^2 + p_i^2}, \vec{p}_i \right), \quad (4.9)$$

where we assumed all neutral particles to be massless photons. For charged tracks in the ROE a mass hypothesis needs to be defined in order to determine the track's energy. After the ROE clean-up we make the following procedure of choosing the mass hypothesis

1. e , if e prob. $> \mu$ prob. and e prob. > 0.9 ,
2. otherwise μ , if μ prob. $> e$ prob. and μ prob. > 0.97 ,
3. otherwise K , if K/π prob. > 0.6 ,

495 4. otherwise π .

We define the square of the missing mass, m_{miss}^2 , which is consistent with zero, if signal-side neutrino is the only missing particle in the event, as shown in Eq. (4.11).

$$p_\nu = p_{miss} = (E_{miss}, \vec{p}_{miss}), \quad (4.10)$$

$$m_{miss}^2 = p_{miss}^2 = p_\nu^2 = m_\nu^2 \approx 0. \quad (4.11)$$

496 Since the detector is not perfect, the distribution of the m_{miss}^2 variable has a non-
 497 zero width. Additionally, a tail is introduced due to missing particles like neutrinos,
 498 other neutral undetected particles such as K_L^0 , or simply missing tracks due to
 499 detection failure. Figure 4.9 shows the distribution of m_{miss}^2 as defined with the
 500 missing four-momentum in Eq. (4.10). Correctly reconstructed candidates, which
 501 come from events where the other B meson decayed via a hadronic decay mode, peak
 502 at zero. If this is not the case, candidates are shifted to larger values of this variable,
 503 even if the event in question is a signal event. For this purpose, we define a subset of
 504 all signal candidates, which come from events where the companion B meson decayed
 505 hadronically and all of its particles were taken into account correctly. We only allow
 506 for missing photons, since they are frequently radiated due to bremsstrahlung effects
 507 from final-state electrons and they do not have such a big impact on the 4-momentum
 508 of the final candidate. We denote this subset as *perfect* signal. This subset is used
 509 to correctly define the clean-up parameters and is not used in any reconstruction
 510 steps since we cannot know in data which neutral particles are actually missing.

511 Due to this fact, we impose a cut on the m_{miss}^2 variable in order to partially discard
 512 candidates with spoiled properties, even if it was in principle a correct combination
 513 of FSP particles on the signal side. The cut was chosen based on the optimization
 514 of FOM, where in this case the definition of S were perfectly reconstructed signal
 515 candidates. The chosen cut value is

516 • $|m_{miss}^2| < 3.0 \text{ GeV}/c^2$,

517 which is also under-optimized at this point due to the same reasons as in the cases
 518 above.

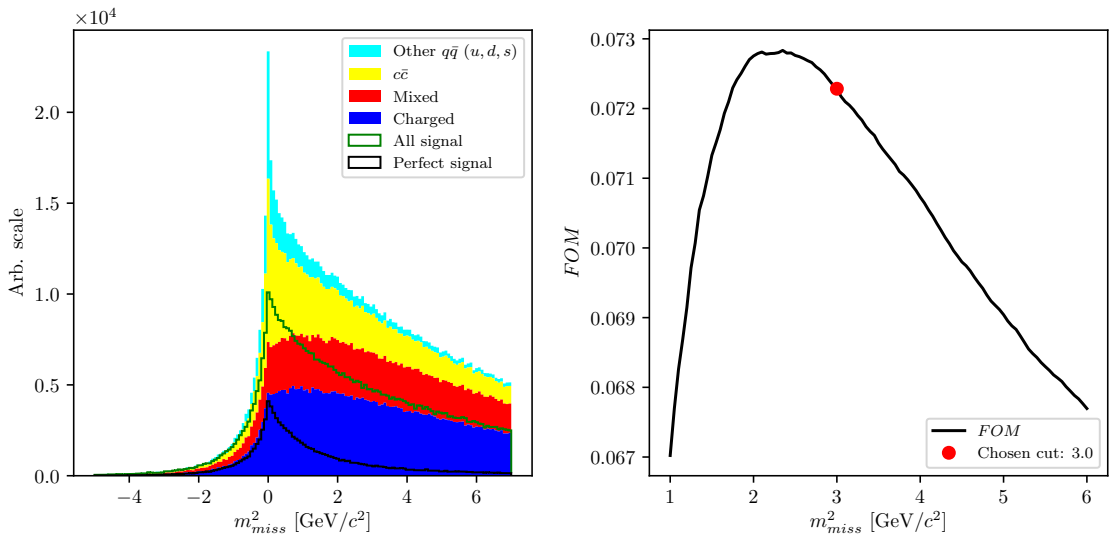

Figure 4.9: Squared missing mass distribution for signal and various types of background. All signal (green) and perfect signal (black) are scaled up equally.

519 The main uncertainty of the neutrino four-momentum, defined in Eq. (4.10),
 520 comes from energy uncertainty. It is a common practice to substitute the miss-
 521 ing energy with the magnitude of the missing momentum, since the momentum
 522 resolution from the measurement is much better, thus redefining the neutrino four-
 523 momentum to

$$p_\nu = (|\vec{p}_{miss}|, \vec{p}_{miss}), \quad (4.12)$$

524 which fixes the neutrino mass to 0 GeV/c².

The newly defined neutrino four-momentum can be added to the four-momentum of the $Y(KK\ell)$ candidate to obtain the full B meson four-momentum and calculate the traditional M_{BC} and ΔE variables

$$\Delta E = E_B - E_{CMS}/2, \quad (4.13)$$

$$M_{BC} = \sqrt{(E_{CMS}/2)^2 - |\vec{p}_B|^2}. \quad (4.14)$$

525 Since the final fit will be performed over ΔE and M_{BC} , we define the fit region

- 526 • $M_{BC} \in [5.1, 5.295]$ GeV/c²,
- 527 • $\Delta E \in [-1.0, 1.3]$ GeV.

528 Figure 4.10 shows the distributions of ΔE (left) and M_{BC} (right) for signal and
 529 major types of background after the pre-cuts. Both signal components are scaled up
 530 with respect to the background components but are in proper scale one to another.
 531 The effects of missing particles are clearly seen based on the shape difference between
 532 all and perfect signal.

Figure 4.10: Distributions of ΔE (left) and M_{BC} (right) for signal and major types of background after the precuts. Both signal components are scaled up with respect to the background components, but are in proper scale one to another. The perfect signal has a much better resolution in both distributions, since the event is perfectly reconstructed.

4.4 Final Stage Optimization

With the charge particle selection and a rough selection of the B meson particles in place, we can now afford to run the reconstruction procedure over all of the 10 streams of the full available Belle generic MC. After obtaining the full reconstructed sample, the first task is to optimize the under-optimized cuts from the pre-selection stage. Repeating the procedure on the full sample results in the FOM shapes shown in Figure 4.11, while the optimal cut values are

- $P(\chi^2, NDF) > 6.0 \times 10^{-3}$,
- $|\cos(\theta_{BY})| < 1.05$.

Figure 4.11: FOM optimization of the vertex fit probability (left) and the $\cos \theta_{BY}$ variable (right) for the full Belle MC sample.

With further optimizations, we will be fine-tuning the signal to background ratio. The most prominent and distinguishable part of our signal is the perfectly reconstructed signal. For this purpose, we define a signal region in ΔE and M_{BC} , where most of our perfectly reconstructed candidates lie. We use this region for all of the following optimization steps in this chapter and also in the background suppression chapter 6 since this allows us to better improve the signal to background ratio where it counts most. The 2D FOM optimization of the optimal ΔE and M_{BC} signal region is shown in Figure 4.12.

The signal region is defined as

- $M_{BC} > 5.271 \text{ GeV}/c^2$,
- $|\Delta E| < 0.126 \text{ GeV}$.

Figure 4.12: 2D FOM optimization of the signal region definition, where the signal in the optimization was represented by perfectly reconstructed candidates.

553 With the signal window defined, we can tighten the cut on m_{miss}^2 , which we
 554 intentionally left loose before the signal categorization. With the FOM optimization
 555 of perfectly reconstructed candidates inside the signal region, shown in Figure 4.13,
 556 the optimal cut on m_{miss}^2 is

557 • $|m_{miss}^2| < 0.975 \text{ GeV}/c^2$.

Figure 4.13: FOM optimization of the optimal m_{miss}^2 cut in the signal region.

4.5 Charge product categorization

The missing information due to an escaping neutrino in our reconstructed channel is replaced by information from the companion B meson. Since this is an untagged reconstruction, the quality of the companion B meson affects the properties of the signal candidate. Perfect reconstruction of a hadronically decayed companion B meson results in pronounced peaks at $\Delta E \approx 0$, $m_{miss}^2 \approx 0$ and $M_{BC} \approx m_B$, while imperfect reconstruction due to any kind of missing particles produces tails, shift or simply a worse resolution of the mentioned distributions. These effects are undesired since they make it harder to separate signal from background.

To remedy this, we look at the charge product of the reconstructed B meson and the ROE object. For correctly reconstructed events, this should have a value of

$$q_{B^\pm} q_{B^\mp} = -1, \quad (4.15)$$

however, this value is distributed due to missing charged particles in the reconstruction. Figure 4.14 shows various signal distributions of ΔE and M_{BC} in arbitrary (left) and normalized (right) scales, with the relative ratios of 67.86 % and 32.14 % for correct and wrong values of the charge product, respectively. We see that correctly reconstructed events represent the majority of signal and also have the best resolution in ΔE and M_{BC} , so we proceed with the analysis by imposing the cut in Eq. 4.15.

While this cut introduces a drop in the signal efficiency of about 32.14 %, it improves the resolution of our signal ΔE and M_{BC} distributions and also the signal to background ratio, where the latter changes from 0.95×10^{-3} to 1.09×10^{-3} .

Figure 4.14: Signal distributions of ΔE and M_{BC} based on the charge product of both B mesons in the event. The plot on the left shows the distributions in an arbitrary scales, while the plot on the right shows the normalized distributions.

4.6 Selection Summary

In this section, one can find the full summary of all final selection cuts in the event reconstruction, from FSP particles up to the B meson.

- FSP particles:

- electrons: $|d_0| < 0.1$ cm, $|z_0| < 1.5$ cm, $p > 0.6$ GeV/ c ,
 $p_{CMS} \in [0.4, 2.6]$ GeV/ c , $eID > 0.9$,

- muons: $|d_0| < 0.1$ cm, $|z_0| < 1.5$ cm, $p_{CMS} \in [0.6, 2.6]$ GeV/ c ,
 $\mu ID > 0.97$,

- 587 – kaons: $|d_0| < 0.15 \text{ cm}, |z_0| < 1.5 \text{ cm}, p_{CMS} < 2.5 \text{ GeV}/c,$
- 588 $K/\pi \text{ ID} > 0.6, K/p \text{ ID} > 0.1,$
- 589 • B meson candidates:
- 590 – standard cuts: $P(\chi^2, DOF) > 6 \times 10^{-3}, |\cos \theta_{BY}| < 1.05, |m_{miss}^2| <$
- 591 $0.975 \text{ GeV}/c^2,$
- 592 – fit region cuts: $\Delta E \in [-1.0, 1.3] \text{ GeV}, M_{BC} \in [5.1, 5.295] \text{ GeV}/c^2,$
- 593 – signal region cuts: $|\Delta E| < 0.126 \text{ GeV}, M_{BC} > 5.271 \text{ GeV}/c^2,$
- 594 – charge categorization: $q_{B^\pm} q_{B^\mp} = -1.$

Chapter 5

Rest of Event Clean-up

Continuing from section 4.3, the description of the ROE clean-up process is described here.

Training the MVA classifiers follows the same recipe for all the steps in this chapter. For each step, we run B meson reconstruction on Signal MC with a generic companion B meson. This way the produced weight files are less likely to be signal-side dependent and can be used also for untagged analyses of other decays. For every correctly reconstructed signal B meson we save the necessary information for each MVA step (i.e. properties of ROE clusters). Only correctly reconstructed B candidates are chosen here, to prevent leaks of information from the signal side to the ROE side.

More information about the MVA training, hyper-parameter optimization and feature importance for each MVA step in this chapter can be found in the Appendix 9.

5.1 Clusters Clean-up

Photons originate from the IP region, travel to the ECL part of the detector in a straight line and produce a cluster. The direction of the photon is determined via the location of the cluster hit in the ECL and the energy of the photon is directly measured via the deposited energy. This way the four-momentum of photons is determined and used in Eq. (4.8).

Most of the photons in events with B mesons come from $\pi^0 \rightarrow \gamma\gamma$ decays. However, a lot of hits in the ECL are also created by photons coming from the beam-induced background or secondary interactions with the detector material. Photons of the first kind should be taken into account when calculating the missing 4-momentum, while the latter kind adds extra energy and momentum which spoils our measured quantities. In the first step of the clusters clean-up, we train an MVA which recognizes good π^0 candidates and apply this information to the daughter photons. This represents a sort of a π^0 origin probability, which peaks at or is equal to 0 for photons not coming from π^0 particles, and peaks at 1 otherwise. This information is used as an additional classifier variable in the next step of the clean-up, where we train to recognize good photons in an event.

5.1.1 π^0 MVA Training

The training dataset of π^0 candidates contains

- 183255 target candidates,

630 • 200000 background candidates,

631 where the definition of a target is that both photon daughters that were used in the
 632 reconstruction of the π^0 are actual photons and real daughters of the π^0 particle.
 633 We use π^0 candidates from the converted Belle particle list and select those with
 634 invariant mass in the range of $M \in [0.10, 0.16]$ GeV. After that we perform a mass-
 635 constrained fit on all candidates, keeping only the ones for which the fit converged.

636 The input variables used in this MVA are

- 637 • p and p_{CMS} of π^0 and γ daughters,
- 638 • fit prob. of the mass-constrained fit, invariant mass and significance of mass
 639 before and after the fit,
- 640 • angle between the photon daughters in the CMS frame,
- 641 • cluster quantities for each daughter photon
 - 642 – E_9/E_{25} ,
 - 643 – theta angle,
 - 644 – number of hit cells in the ECL,
 - 645 – highest energy in cell,
 - 646 – energy error,
 - 647 – distance to closest track at ECL radius.

648 The classifier output variable is shown in Figure 5.1.

Figure 5.1: Classifier output of the π^0 training for signal and back-ground π^0 candidates.

649 The distributions for all input variables and their correlations for signal and back-
 650 ground candidates can be found in Appendix A for all steps of the ROE clean-up.

5.1.2 γ MVA Training

In this MVA training, we take the π^0 classifier output of the previous training as an input in order to train a classifier to distinguish between good and bad photons. The π^0 probability information from the previous step is applied to all photon pairs which pass the same π^0 cuts as defined in the previous step. Since it's possible to have overlapping pairs of photons, the π^0 probability is overwritten in the case of a larger value, since this points to a greater probability of a correct photon combination. On the other hand, some photon candidates fail to pass the π^0 selection, these candidates have a fixed value of π^0 probability equal to zero.

The training dataset of γ candidates contains

- 171699 target candidates,
- 177773 background candidates,

where the definition of a target is that the photon is an actual photon which is related to a primary MC particle. This tags all photon particles from secondary interactions as background photons. We use the converted γ candidates from the existing Belle particle list.

The input variables used in this MVA are

- p and p_{CMS} of γ candidates,
- π^0 probability,
- cluster quantities
 - E_9/E_{25} ,
 - theta angle,
 - number of hit cells in the ECL,
 - highest energy in cell,
 - energy error,
 - distance to closest track at ECL radius.

The classifier output variable is shown in Figure 5.2.

Figure 5.2: Classifier output of the γ training for signal and background γ candidates.

678 With the final weights for photon classification in hand, we apply them to the
 679 photon particle list. The cut optimization is shown in Figure 5.3 (left), with the
 680 optimal cut on the γ classifier output at

- 681 • $BDT_\gamma > 0.5045$.

682 Figure 5.3 (right) shows the LAB frame momentum of the photons before and
 683 after the cut in logarithmic scale. The signal efficiency and background rejection at
 684 this clean-up cut are

- 685 • Signal efficiency: $\epsilon_{SIG} = 83.2\%$,
- 686 • Background rejection: $1 - \epsilon_{BKG} = 81.2\%$.

Figure 5.3: The FOM of the classifier output optimization (left) and momentum magnitude in the LAB frame of signal and background photon candidates before and after the optimal cut (right).

687 The event is now considered to be clean of extra clusters.

688 5.2 Tracks Clean-up

689 Charged particles leave hits in the detector, which are then grouped into tracks
 690 by advanced tracking algorithms. The track is fitted and the track momentum is
 691 determined. With the help of particle identification information (PID), we are able
 692 to make an intelligent decision about the mass hypothesis of the particle and thus
 693 reconstruct the charged particle's four-momentum, which is then added in the loop
 694 in Eq. (4.8).

695 Most of the quality (good) tracks, which come from physics event of interest,
 696 come from the IP region, where the collisions occur. Cleaning up the tracks is a
 697 more complex procedure than cleaning up the clusters. The following facts need to
 698 be taken into account

- 699 (a) good tracks can also originate away from the IP region, due to decays of long-
 700 lived particles, such as $K_S^0 \rightarrow \pi^+ \pi^-$,
- 701 (b) charged particles from background sources produce extra tracks or duplicates,
- 702 (c) low momentum charged particles can curl in the magnetic field and produce
 703 multiple tracks,
- 704 (d) secondary interactions with detector material or decays of particles in flight can
 705 produce "kinks" in the flight directory, resulting in multiple track fit results per
 706 track.

707 Schematics of all the cases mentioned above are shown in Figure 5.4.

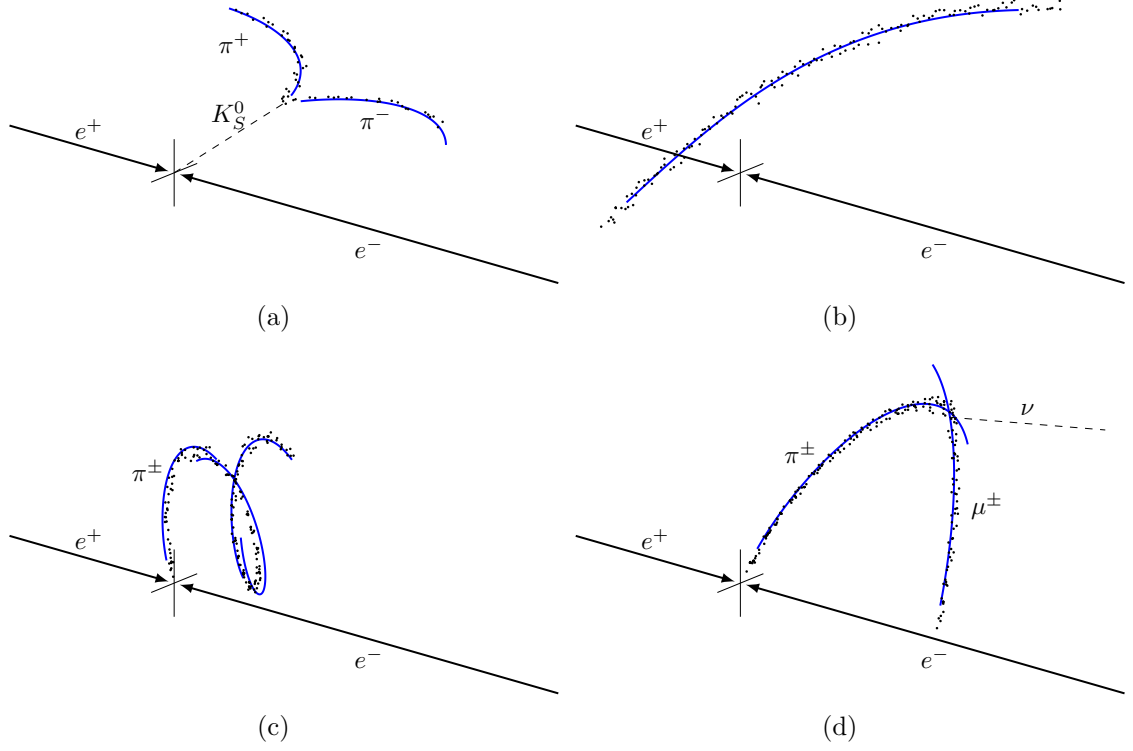

Figure 5.4: (a) Tracks from long-lived neutral particles, which decay away from the IP region, (b) Random tracks from background which are reconstructed, (c) Low-momentum particles which curl in the magnetic field, (d) in-flight decays of particles, which produce a kink in the trajectory.

It is obvious that tracks from the same momentum source should only be taken into account once, or, in case of background tracks, not at all. Such tracks will from this point on be denoted as *extra* tracks, because they add extra four-momentum to our final calculations in Eq. (4.8). At the same time, we have to take care that we don't identify *good* tracks as *extra* tracks. Both of these cases have negative impacts on the final resolution of all variables which depend on information from ROE.

5.2.1 Tracks from Long-lived Particles

The first step in tracks clean-up is taking care of tracks from long-lived particles, such as $K_S^0 \rightarrow \pi^+\pi^-$, $\gamma \rightarrow e^+e^-$ and decays of Λ baryons. Here we only focus on K_S^0 , since they are the most abundant. This step is necessary because of the π^\pm particles, coming from the K_S^0 decays, have large impact parameters, which is usually a trait of background particles. In order to minimize confusion from the MVA point-of-view, these tracks are taken into account separately.

We use the converted K_S^0 candidates from the existing Belle particle list and use a pre-trained Neural Network classifier in order to select only the good K_S^0 candidates. Figure 5.5 shows the distribution of the K_S^0 invariant mass for signal and background candidates, before and after the classifier cut. The momentum of selected K_S^0 candidates is added to the ROE, while the daughter tracks are discarded from our set.

Figure 5.5: Invariant mass of the K_S^0 candidates before (dashed lines) and after (solid lines) the cut on the Neural Network classifier for signal (green) and background candidates (red). Signal peaks at nominal K_S^0 mass, while background covers a wider region.

727 The signal efficiency and background rejection for K_S^0 candidates after this cut
 728 and on the full range are

- 729 • Signal efficiency: $\epsilon_{SIG} = 80.7 \%$,
- 730 • Background rejection: $1 - \epsilon_{BKG} = 99.4 \%$.

731 5.2.2 Duplicate Tracks

732 All good tracks at this point should be coming from the IP region, since we took
 733 care of all the good tracks from long-lived particle decays, therefore we apply a cut
 734 on impact parameters for all the remaining tracks

- 735 • $|d_0| < 10 \text{ cm}$ and $|z_0| < 20 \text{ cm}$

736 and proceed with the clean-up of track duplicates.

737 Defining a duplicate track pair

738 In this step, we wish to find a handle on secondary tracks from low momentum
 739 curlers and decays in flight. The main property for these cases is that the 3D
 740 opening angle between such two tracks is very close to 0° or 180° , since tracks
 741 deviate only slightly from the initial direction, but can also be reconstructed in the
 742 opposite way. Figure 5.6 shows the distribution of the angle between two tracks in
 743 a single pair for random track pairs and duplicate track pairs, where the latter were
 744 reconstructed as two same-sign or opposite-sign tracks.

Figure 5.6: Distribution of the angle between two tracks in a single pair for random track pairs (green) and duplicate track pairs, where the latter were reconstructed as two same-sign (blue) or opposite-sign tracks (red).

745 If the particle decayed mid-flight or produced multiple tracks due to being a low-
 746 momentum curler, then, as the name suggests, these particles most likely had low
 747 momentum in the transverse direction, p_T . Since both tracks originate from the
 748 same initial particle, the momentum difference should also peak at small values.
 749 Figure 5.7 shows the momentum and momentum difference of tracks which belong
 750 to a random or a duplicate track pair.

Figure 5.7: Distribution of transverse momentum p_T (left) and transverse momentum difference Δp_T (right) for all tracks coming from random (green) or duplicate track pairs (red). The plot on the right already includes the cut on p_T from the plot on the left.

We impose a cut of

- $p_T < 0.5 \text{ GeV}/c$,
- $|\Delta p_T| < 0.1 \text{ GeV}/c$,

in order to cut down the number of random track pairs, while retaining a high percentage of duplicate track pairs. After all the cuts defined in this chapter, the final distribution of the angle between two tracks is shown in Figure 5.8.

Figure 5.8: Distribution of the angle between two tracks in a single pair after applying the selection cuts defined in this subsection. The distributions are shown for random track pairs (green) and duplicate track pairs, where the latter were reconstructed as two same-sign (blue) or opposite-sign tracks (red).

Training the duplicate track pair MVA

This final sample of track pairs is now fed into an MVA, which is trained to recognize duplicate track pairs over random ones. The training dataset contains

- 113707 target candidates,
- 190314 background candidates,

where the definition of a target is that the track pair is a duplicate track pair.

The input variables used in this MVA are

- angle between tracks,
- track quantities
 - impact parameters d_0 and z_0 ,
 - transverse momentum p_T ,
 - helix parameters and helix parameter errors of the track,

- 769 – track fit p -value,
- 770 – number of hits in the SVD and CDC detectors

771 The classifier is able to distinguish between random and duplicate track pairs in
 772 a very efficient manner, as shown in Figure 5.9.

Figure 5.9: Classifier output of the track pair training for random track pairs and duplicate track pairs.

773 The FOM function for optimal cut selection is shown in Figure 5.10 (left), along
 774 with the angle between the two tracks before and after the optimal cut (right). The
 775 optimal cut for duplicate track selection is

- 776 • $BDT_{duplicate} > 0.9985$.

777 The signal efficiency and background rejection for duplicate pair candidates after
 778 this cut is

- 779 • Signal efficiency: $\epsilon_{SIG} = 87.2 \%$,
- 780 • Background rejection: $1 - \epsilon_{BKG} = 98.8 \%$,

781 where signal and background represent duplicate and random track pairs, respec-
 782 tively.

Figure 5.10: The optimization of the FOM function for the cut on classifier output (left) and distribution of the angle between two tracks in a single pair before (dashed) and after (solid) applying the optimal cut on the output classifier for random and duplicate track pairs (right).

Defining duplicate tracks

What remains now is to decide which track from the duplicate track pair to keep and which to discard. For this purpose, we apply duplicate pair-level information to each track in the pair in the form of

$$\Delta f = f_{this} - f_{other}, \quad (5.1)$$

where f is an arbitrary variable from the list of track quantities in section 5.2.2. From the point-of-view of *this* track, a track is more *duplicate*-like if the following is true

- $\Delta d_0, \Delta z_0 > 0$ (*this* track further away from the IP region),
- $\Delta p_T, \Delta p_Z < 0$ (*this* track has lower momentum),
- $\Delta N_{SVD}, \Delta N_{CDC} < 0$ (*this* track has less hits in the SVD and CDC),

Additionally we define an MC truth variable

$$\Delta \chi^2 = \chi_{this}^2 - \chi_{other}^2, \quad \chi^2 = \sum_{i=x,y,z} \frac{(p_i - p_i^{MC})^2}{\sigma(p_i)^2}, \quad (5.2)$$

where we compare all components of track momentum to the true values. If $\Delta \chi^2 > 0$, then *this* track has a higher probability of being a duplicate track and should be discarded.

However, it turns out that solving this problem is not as simple as discarding one track and keeping the other one. An additional complication here is that we can have more than one extra track from the same initial particle, which leads to track

pairs where both tracks are track duplicates. For example, if we have the following case

$$\begin{aligned}
t_1 &: \text{good track}, \\
t_2 &: \text{extra track}, \\
t_3 &: \text{extra track}, \\
\text{pair}_1 &: (t_1, t_2), \\
\text{pair}_2 &: (t_1, t_3), \\
\text{pair}_3 &: (t_2, t_3),
\end{aligned}$$

where t_1 is the original track and t_2 and t_3 are extra tracks, with t_3 being even more duplicate-like with respect to t_2 . Here tracks t_2 and t_3 should be discarded while t_1 should be kept. We can achieve this if we overwrite existing pair-level information in the tracks for cases where the variable difference Δf is more duplicate-like. If we follow the same example, we could fill information about the property f in six different orders.

$$\begin{aligned}
1. (t_1, t_2*) &\rightarrow (t_1, t_3*) \rightarrow (t_2*, t_3*), \\
2. (t_1, t_2*) &\rightarrow (t_2*, t_3*) \rightarrow (t_1, t_3*), \\
3. (t_1, t_3*) &\rightarrow (t_2, t_3*) \rightarrow (t_1, t_2*), \\
4. (t_1, t_3*) &\rightarrow (t_1, t_2*) \rightarrow (t_2*, t_3*), \\
5. (t_2, t_3*) &\rightarrow (t_1, t_3*) \rightarrow (t_1, t_2*), \\
6. (t_2, t_3*) &\rightarrow (t_1, t_2*) \rightarrow (t_1, t_3*),
\end{aligned}$$

797 where the "*" symbol denotes when a track is recognized as a duplicate track
798 with respect to the other track. We see that no matter the order, both t_2 and t_3 get
799 recognized as duplicate tracks correctly. If you are a part of my defense committee
800 and actually read this before my thesis defense, let me know, I owe you a bottle of
801 whiskey.

802 Training the duplicate track MVA

803 The training procedure is similar as before. The sample of tracks from duplicate
804 track pairs is now fed into an MVA, which is trained to distinguish duplicate tracks
805 from good tracks. The training dataset contains

- 806 • 84339 target candidates,
- 807 • 68280 background candidates,

808 where the definition of a target is that the track is a duplicate track.

809 The input variables used in this MVA are

- 810 • theta angle of the track momentum,
- 811 • track quantities
 - 812 – impact parameters d_0 and z_0 and their errors,
 - 813 – CMS frame momentum p_{CMS} and momentum components p_T and p_z

- 814 – number of hits in the SVD and CDC detectors
- 815 – track fit p -value,
- 816 • pair-level information
- 817 – Δd_0 , Δz_0 , ΔN_{CDC} , ΔN_{SVD} , Δp_T , Δp_z , Δp -value.

818 The weights from this training are applied to the tracks, where now each track
 819 has a certain probability of being a duplicate track. We then compare these values
 820 between both tracks in each track pair as

$$\Delta BDT_{final} = BDT_{final}^{this} - BDT_{final}^{other}, \quad (5.3)$$

821 which is again applied to all track pairs and overwritten for tracks which are more
 822 duplicate-like. The classifier output and the classifier output difference for each
 823 track are shown in Figure 5.11.

Figure 5.11: Classifier output of the MVA training for curling track recognition (left) and difference of the classifier output, calculated for each track in a track pair (right).

824 Finally, we select all duplicate tracks which survive the cut

$$\Delta BDT_{final} > 0 \quad (5.4)$$

825 and discard them from our ROE. We can check the performance of our duplicate
 826 track classifier by applying the procedure on a validation sample of duplicate track
 827 pairs and compare the predicted result with the truth, based on Eq. (5.2). Table 5.1
 828 shows the performance of the duplicate track recognition in the form of percentages
 829 of correctly and incorrectly identified duplicate and original tracks. The model seems
 830 to perform well and the event is now considered to be clean of duplicate tracks.

	Predicted duplicate track	Predicted good track
Duplicate track	83.07 %	22.62 %
Good track	16.93 %	77.38%

Table 5.1: Ratios of correctly classified and misclassified tracks.

5.3 Belle Clean-up

For comparison, we define the Belle clean-up, used standardly at Belle, which is much simpler and relies only on a set of rectangular cuts for neutral particles as well as charged ones. This clean-up procedure is not applied in addition to our ROE clean-up, but separately, only for comparison.

In case of photons, a single cut on photon energy is applied, depending on the region where the photon hit the relevant part of the detector. The photon cuts are summarized in Table 5.2.

	$17^\circ < \theta < 32^\circ$	$32^\circ < \theta < 130^\circ$	$130^\circ < \theta < 150^\circ$
E_γ	$> 100 \text{ MeV}$	$> 50 \text{ MeV}$	$> 150 \text{ MeV}$

Table 5.2: Photon selection for the Belle clean-up procedure. Different cuts are applied on photons in different parts of the detector

In case of tracks, pairs are selected which satisfy the following criteria:

- $p_T < 275 \text{ MeV}/c$,
- $\Delta p = |\vec{p}_1 - \vec{p}_2| < 100 \text{ MeV}/c$,
- $\cos \theta(\vec{p}_1, \vec{p}_2) < 15^\circ$ for same sign,
- $\cos \theta(\vec{p}_1, \vec{p}_2) > 165^\circ$ for opposite sign.

Of the two tracks, the one with a larger value of formula in Eq. 5.5 is discarded. The remaining tracks in the event then need to satisfy the conditions described in Table 5.3.

$$(\gamma|d_0|)^2 + |z_0|^2, \quad \gamma = 5. \quad (5.5)$$

	$p_T < 250 \text{ MeV}/c$	$250 \text{ MeV}/c < p_T < 500 \text{ MeV}/c$	$p_T > 500 \text{ MeV}/c$
$ d_0 $	$< 20 \text{ cm}$	$< 15 \text{ cm}$	$< 10 \text{ cm}$
$ z_0 $	$< 100 \text{ cm}$	$< 50 \text{ cm}$	$< 20 \text{ cm}$

Table 5.3: Photon selection for the Belle clean-up procedure. Different cuts are applied on photons in different parts of the detector

5.4 Clean-up Results

In this section, the results of the ROE clean-up are shown. It is obvious that cleaning up the event affects the shape of various distributions, especially ΔE and M_{BC} , which we are most interested in. Since the reconstruction procedure includes cuts on the cleaned-up variables, the clean-up also affects the efficiency of the reconstructed sample, not only the resolution.

We compare the clean-up setup, defined in this analysis, to the standard clean-up used by Belle, and to a default case, where no clean-up was applied at all. We apply

855 the clean-up procedure to our signal MC sample with all the applied cuts, defined in
 856 section 4.6, except for the signal categorization cuts. Figure 5.12 (left) shows signal
 857 candidate distributions of ΔE and M_{BC} for various clean-up setups. Focusing on
 858 the ROE clean-up, we see an improvement in resolution in both observed variables
 859 and an overall decrease in efficiency. The efficiency decrease is expected since the
 860 cleaned-up variables are able to better isolate the perfectly reconstructed candidates
 861 and discard the non-perfect candidates. In fact, the efficiency of the perfectly re-
 862 constructed candidates increases after the ROE clean-up, as shown in Figure 5.12
 863 (right). The signal MC sample after in case of the Belle clean-up also shows a slight
 864 improvement in the resolution, but looking at the perfectly reconstructed candi-
 865 dates we see that this clean-up procedure is not optimal. Table 5.4 shows ratios
 866 of efficiencies and $FWHM$'s of the clean-up procedures for the perfect signal with
 867 respect to the default case, based on the ΔE distribution. While both the Belle and
 868 ROE clean-up improve the resolution, ROE clean-up performs significantly better
 869 and also increases the amount of the perfectly reconstructed candidates in the final
 870 sample.

Figure 5.12: ΔE and M_{BC} distributions for various types of clean-up procedures. The figures on the left are shown for the full signal sample after the stated cuts, while the figures on the right are shown for the perfectly reconstructed signal candidates. For ROE clean-up, the procedure seems to improve resolution as well as increase the amount of perfectly reconstructed candidates, relative to the default case.

	Efficiency ratio	FWHM ratio
Belle clean-up	28.5 %	75.0 %
ROE clean-up	140.1 %	35.0 %

Table 5.4: Comparison of efficiencies and $FWHM$'s of ROE and Belle clean-up setups with respect to the default case (no clean-up).

871 Another variable which heavily depends on the clean-up is the charge product of

872 the signal and companion B meson candidate, already defined in Eq. (4.15), shown
 873 in Figure 5.13 for various clean-up procedures. The figure shows an improved reso-
 874 lution of the distribution, which means that candidates migrate to the correct value
 875 of the charge product after the clean-up. Looking at the perfectly reconstructed
 876 candidates we again see the increase in the bin corresponding to the correct charge
 877 product. As a cross-check, we can also look at ΔE and M_{BC} variables for each
 878 value of the charge product. These plots are shown for the full signal MC sample in
 879 Figure 5.14 and they show a clear resolution improvement for the correct value of
 880 the charge product in the case of the ROE clean-up. For other values of the charge
 881 product, there also seems to be a small improvement for both cases of clean-up, but
 882 it is negligible compared to the plots in the second column. This supports our choice
 883 of signal categorization, defined in section 4.5, where we select only candidates with
 884 the correct value of the charge product.

Figure 5.13: Distribution of the charge product of both B mesons for various types of clean-up procedures, shown on the full signal MC (left) and for the perfectly reconstructed signal candidates (right). For ROE clean-up, the procedure seems to increase the number of perfectly reconstructed candidates.

Figure 5.14: Distributions of ΔE (top) and M_{BC} (bottom) for various types of clean-up procedures, split by specific values of the charge product, shown for the full signal MC. There is a significant improvement in resolution after ROE-clean-up for the case of the correct value of the charge product.

5.5 ROE Clean-up Validation

The ROE clean-up seems to perform well on signal MC based on the results in the previous section. However, it is necessary to make sure that this procedure performs as well on other simulated and measured data, which is done in this section. The clean-up procedure is validated on the control sample,

$$B^+ \rightarrow \bar{D}^0 \ell^+ \nu, \quad D^0 \rightarrow K^+ K^-,$$

which was already defined in section 2.2. The control candidates are reconstructed in the same manner as the signal candidates. In addition to the same cuts applied as in the previous section, we also apply a selection to make the control sample more significant. We discard all candidates which fail to pass the cut on invariant mass of the two kaons

$$1.849 \text{ GeV}/c^2 < m_{KK} < 1.879 \text{ GeV}/c^2 \quad (5.6)$$

as shown in Figure 5.15.

Figure 5.15: Distributions of m_{KK} for the full MC dataset. The black lines represent the cut on region in the m_{KK} distribution where the control sample is enhanced.

With the control sample selection determined, we now run the reconstruction with and without the ROE clean-up procedure on MC and data. For the purpose of this validation, we only run the reconstruction over 1 stream of the full available generated MC.

The effects of the ROE clean-up are shown in Figure 5.16. We see that data and MC agree well, and evidently even better after the clean-up procedure. The control sample resolution seems very poor in the case without the clean-up, but it improves significantly if the clean-up procedure is applied, as expected. The simulated background also seems to gain an improvement in the resolution, but this is likely due to the background consisting of similar candidates as the control sample. This means that the clean-up performs as expected due to the nature of the decays and does not arbitrarily shape the background to be more signal like. Additionally, it should be pointed out that, after the clean-up, the simulated background resolution is worse compared to the control decay resolution, while this is not the case if the clean-up procedure is not performed.

Figure 5.16: Distributions of ΔE (top) and M_{BC} bottom for the case without (left) and with ROE clean-up (right). The resolution of the control sample is improved and the MC and data agree well in all aspects. While the simulated background resolution is also improved, it is worse compared to the resolution of the control sample.

907 To perform the clean-up validation in greater detail we also compare the data and
 908 MC agreement in bins of the charge product of the two B mesons. Figure 5.17 shows
 909 the cleaned-up versions of ΔE and M_{BC} for each charge product bin in the same
 910 manner as shown in the previous section. We see that the MC and data agreement
 911 persists in all cases.

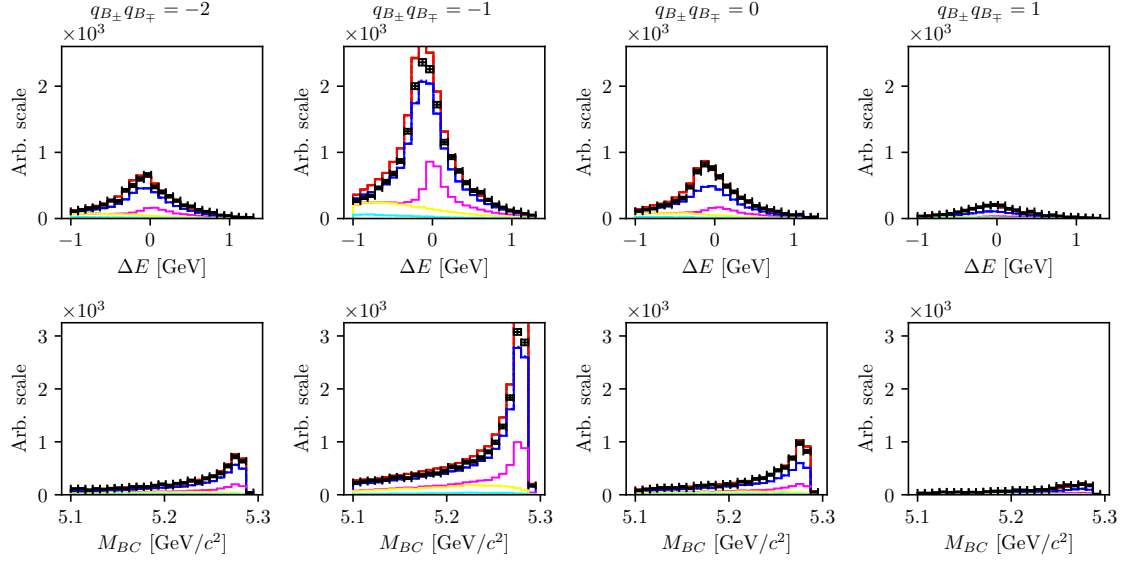

Figure 5.17: Distributions of ΔE (top) and M_{BC} (bottom) split in bins of the charge product of the two B mesons.

912 The ROE clean-up procedure seems to perform well. It significantly improves the
 913 resolution of the signal/control candidates and increases the amount of perfectly
 914 clean events. The clean-up procedure was also applied to data and no disagreement
 915 with respect to the simulated MC samples was found. This means that the procedure
 916 does not differ between MC and data and does not affect them differently. The
 917 procedure was therefore validated in great detail and is suitable to be used in this
 918 analysis.

Chapter 6

Background Suppression

This chapter shows the procedure in suppressing various kinds of backgrounds by applying cuts on MVA classifier outputs. More information about the MVA training, feature importance and hyper-parameter optimization for each MVA step in this chapter can be found in the Appendix 10.

6.1 Resonant Background

In this analysis we study decays with kaons in the final state. This means that standard procedures in $b \rightarrow u$ analyses in order to suppress $b \rightarrow c$ backgrounds, such as K -veto, are not possible. As a consequence, our final sample consists of combinations of K pairs coming also from $b \rightarrow c$ sources, such as $D^0 \rightarrow K^+ K^-$. Such candidates usually have resonance-like properties in the two-kaon invariant mass spectrum. Figure 6.1 shows this invariant mass spectrum of two kaons, m_{KK} , where obvious resonant structures are present from sources like

- $\phi \rightarrow K^+ K^-$ (sharp resonance at $\sim 1.019 \text{ GeV}/c^2$),
- $D^0 \rightarrow K^+ K^-$ (sharp peak at $\sim 1.864 \text{ GeV}/c^2$),
- $D^0 \rightarrow K^+ \pi^-$ (wide, shifted peak, due to kaon miss-identification).

In order to suppress these resonant backgrounds, while studying signal or control decay, we impose a set of the following cuts

- Signal cut: $|m_{KK} - m_\phi| > \Delta_\phi$, $|m_{KK} - m_{D^0}| > \Delta_{D^0}$, $|m_{K\pi} - m_{D^0}| > \Delta_{D^0}$,
- Control cut: $|m_{KK} - m_{D^0}| \leq \Delta_{D^0}$, $|m_{K\pi} - m_{D^0}| > \Delta_{D^0}$,

where m_{KK} is the KK invariant mass and $m_{K\pi}$ is the invariant mass of KK , where the kaon's mass, which has the same charge as the B meson, was given the mass of the π^0 particle, and where $m_\phi \approx 1.019 \text{ GeV}/c^2$ and $m_{D^0} \approx 1.864 \text{ GeV}/c^2$ are nominal masses of the ϕ and D^0 mesons, and $\Delta_\phi \approx 8 \times 10^{-3} \text{ GeV}/c^2$ and $\Delta_{D^0} \approx 1.5 \times 10^{-2} \text{ GeV}/c^2$ are symmetric cut widths around the nominal mass values for the ϕ and D^0 mesons, respectively. By imposing the signal or control cut on our data, we are able to efficiently isolate the desired subset, which is very useful for further studies of the control decay. Table 6.1 shows the subsample efficiency after applying either of the cuts.

	$\epsilon(\text{Signal cand.})$	$\epsilon(\text{Control cand.})$	$\epsilon(\phi \text{ resonance cand.})$
Signal cut	95.4%	4.0%	13.6%
Control cut	1.9%	96.0%	0.0%

Table 6.1: Various subset efficiencies after imposing the signal or control cut on the KK invariant mass.

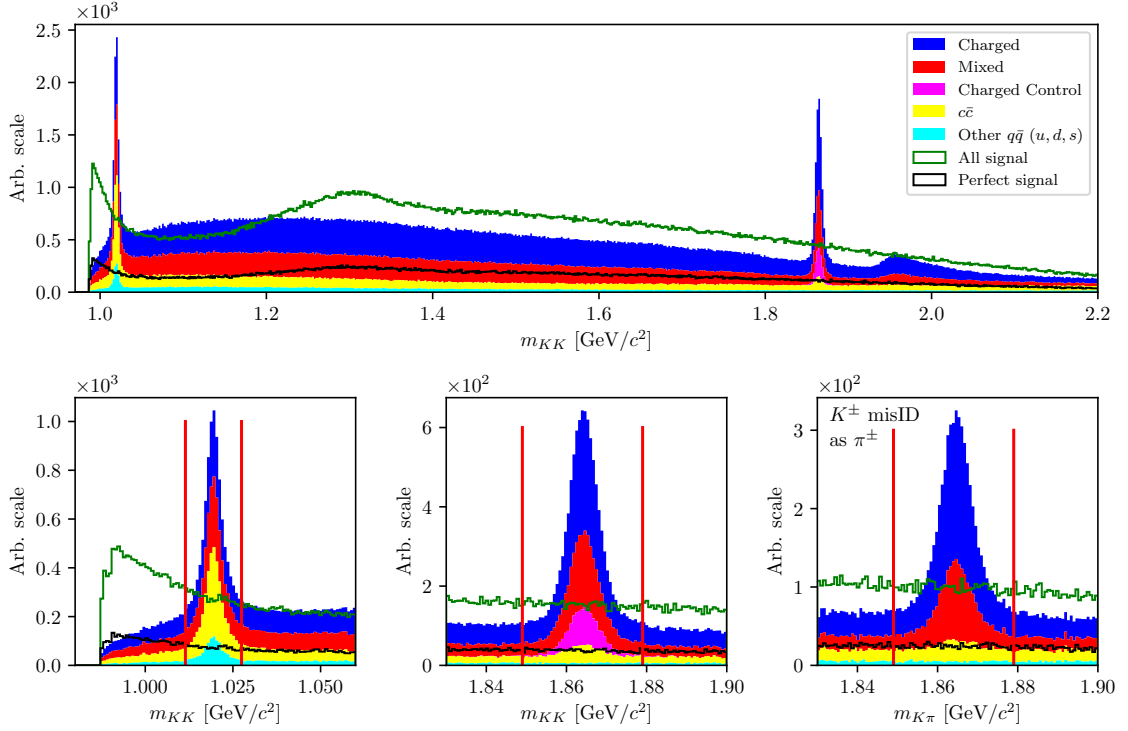

Figure 6.1: Invariant mass of two correctly reconstructed kaons (left) and invariant mass of two kaons, where one was miss-identified as a pion (right). Signal (green) and perfect signal (black) are equally scaled up.

6.2 Continuum Suppression

Continuum background are physics processes where continuum states are produced in electron and positron collisions

$$e^+e^- \rightarrow q\bar{q},$$

where $q = u, d, s$ or c , and are a sizable contribution to $B\bar{B}$ events. Additionally to kinematic constraints to separate $e^+e^- \rightarrow \Upsilon(4S) \rightarrow B\bar{B}$ decays from $e^+e^- \rightarrow q\bar{q}$, properties of the "event shape" are also often used, because phase-space distributions of decayed particles differ for these two processes. Continuum background events are generated in a back-to-back way in the CMS frame, so hadrons produced in the quark fragmentation possess only a small transverse momentum compared to the initial momentum magnitude. This leads to a spatially confined, jet-like structure. On the other hand, B mesons from $B\bar{B}$ events are produced almost at rest in the

CMS frame. Their decay products form an isotropic distribution in the detector, which yields a spherical event shape.

6.2.1 Characteristic Variables

Information on the phase-space distribution of decay particles is obtained in a number of different ways. In this subsection different characteristic variables are presented which are used in the MVA training. They all focus on kinematic and shape differences between the two processes, which we want to discriminate.

Thrust and Related Variables

It is possible to define a thrust axis \vec{T} for a collection of N momenta p_i as a unit vector along which their total projection is maximal. Thrust axis \vec{T} can be obtained by maximizing the expression

$$\vec{T} = \frac{\sum_i |\vec{T} \cdot \vec{p}_i|}{\sum_i |\vec{p}_i|}. \quad (6.1)$$

In this case, a related variable is $|\cos \theta_T|$, where θ_T is the angle between the thrust axis of the momenta from B meson decay particles and the thrust axis of all particles in the ROE. Since both B mesons in $B\bar{B}$ events are produced at rest, their decay particles, and consequentially their thrust axes, are uniformly distributed in the range $[0, 1]$. On the other hand, decay particles from continuum events follow the direction of the jets in the event. As a consequence, the thrusts of both the B meson and the ROE are strongly directional and collimated, which results in a large peak at $|\cos \theta_T| \approx 1$. Additionally, one can also use the variable $|\cos \theta_{T,B}|$, which is the thrust axis between the B candidate and the beam axis. For B candidates from $B\bar{B}$ events, this distributions is again uniformly distributed, while for candidates from continuum events this distribution follows the distribution of the jets with the function $1 + \cos^2 \theta_{T,B}$. Figure 6.2 shows the distributions of $|\cos \theta_T|$ (left) and $|\cos \theta_{T,B}|$ (right) for different B meson candidates.

Figure 6.2: Distributions of $|\cos \theta_T|$ (left) and $|\cos \theta_{T,B}|$ (right) for different B meson candidates.

CLEO Cones

CLEO cones have been introduced by the CLEO collaboration [10] and are an additional specific tool to provide optimal background discrimination. They are nine variables corresponding to the momentum flow around the thrust axis of the B meson candidate, binned in nine cones of 10° around the thrust axis, as illustrated in Figure 6.3.

Figure 6.3: Concept of CLEO cones. \vec{T} denotes the thrust axis of the B meson candidates in the event. Each variable corresponds to a momentum flow around the thrust axis in steps of 10° .

KSFW Moments

Fox-Wolfram moments are another useful parametrization of phase-space distribution of energy flow and momentum in an event. For a collection of N momenta p_i , the k -th order normalized Fox-Wolfram moment R_k is defined as

$$R_k = \frac{H_k}{H_0} = \frac{1}{H_0} \sum_{i,j} |p_i| |p_j| P_k(\cos \theta_{ij}), \quad (6.2)$$

where θ_{ij} is the angle between p_i and p_j , and P_k is the k -th order Legendre polynomial. For events with two strongly collimated jets, R_k takes values close to 0 (1) for odd (even) values of k , so these moments provide a convenient discrimination between $B\bar{B}$ and continuum events.

Belle developed a refined generation of Fox-Wolfram moments, called Kakuno-Super-Fox-Wolfram (KSFW) moments to further suppress the continuum background. There are 17 different KSFW moments which are grouped into R_k^{so} , R_k^{oo} and R_k^{ss} [11]. The latter ones are excluded due to correlations with B meson specific variables.

6.2.2 MVA Training

Most of the characteristic variables, described in section 6.2.1, were taken together in order to train a single MVA classifier for continuum suppression. All characteristic variables were checked for possible q^2 , M_{BC} or ΔE correlation. Variables with significant correlation or complex shapes in the correlation distribution were discarded from the training set, since they would have introduced unwanted dependence on the unreliable model, ISGW2, used for signal MC generation. Additionally, all of the characteristic variables in our set do not depend on the signal mode, they only differ in the kinematic and topological aspects of $B\bar{B}$ and continuum background events.

The training dataset consisted of 2×10^5 candidates, where 50 % of the candidates are correctly reconstructed signal events, 25 % are $u\bar{u}$, $d\bar{d}$ and $s\bar{s}$ background with expected proportions, and 25 % is $c\bar{c}$ background. Since the full Belle dataset is experiment dependent, we construct the training dataset by proportionally sampling each MC dataset, corresponding to the appropriate experiment number.

The training variable set consisted of

- B meson direction and thrust related variables
 - magnitude of thrust axes of B and ROE ,
 - cosine of the angle between the thrust axis of B and thrust axis of ROE ,
 - cosine of the angle between the thrust axis of B and beam direction,
 - reduced Fox-Wolfram moment R_2 ,
- all 9 CLEO Cones
- KSFW Moments
 - $R_{01}^{so}, R_{02}^{so}, R_{03}^{so}, R_{04}^{so}$,
 - $R_{10}^{so}, R_{12}^{so}, R_{14}^{so}$,
 - $R_{20}^{so}, R_{22}^{so}, R_{24}^{so}$,
 - $R_0^{oo}, R_1^{oo}, R_2^{oo}, R_3^{oo}, R_4^{oo}$,
- FlavorTagging variables
 - qp of e, μ, ℓ ,
 - qp of intermediate e, μ, ℓ ,
 - qp of $K, K/\pi$, slow pion, fast hadron,
 - qp of maximum P^*, Λ , fast-slow-correlated (FSC),
- Other
 - $\Delta z, \Delta t$.

Figure 6.4 shows the classifier output for various types of background, all in expected MC proportions. B meson candidates from continuum background are dominant at lower values, while candidates from $B\bar{B}$ events populate the region with higher values.

Figure 6.4: Continuum suppression classifier output for signal and various types of background. B candidates from continuum events dominate the lower region, while candidates from $B\bar{B}$ dominate in the upper region of the classifier output.

6.3 $B\bar{B}$ Suppression

After separating continuum background from $B\bar{B}$ events, the next step is to train an MVA classifier to recognize our signal candidates among the candidates of other $B\bar{B}$ background. $B\bar{B}$ background consists of

- $b \rightarrow c\ell\nu$ background,
- $b \rightarrow u\ell\nu$ background,
- Other rare decays (radiative, penguin, rare 2- and 3-body decays, ...).

Similarly, the training dataset for this classifier consisted of 2×10^5 candidates, where 50 % of the candidates are correctly reconstructed signal events. The remaining part of the training dataset consists of all background, not including the control sample, because we are not interested in suppressing it directly. The background part of the dataset consists of 75 % charged and neutral $B\bar{B}$ events in equal proportions, whereas the remaining 25 % is equally populated with charged and neutral $B\bar{B}$ events from $b \rightarrow u\ell\nu$ and other rare decays. The training dataset was proportionally sampled in the same manner as described in section 6.2.2.

In order to separate this kind of background, we must be careful not to introduce correlations with the fit variables (ΔE , M_{BC}) or any kind of model dependence (correlation with q^2). This means that we can not use any information of the decay particles or the candidate, which is of kinematics nature, such as decay particles momenta, decay angles or other variables with such behavior.

The training variable set consisted of

- fit probability of $P(\chi^2, DOF)$ of the signal candidate and the ROE side, separately,

- 1062 • $\cos \theta_{BY}$ from Eq. (4.4),
- 1063 • \cos of the angle between momentum and vertex of X ,
- 1064 where $X \in [KK, KK\ell, KK\ell\nu]$,
- 1065 • FlavorTagger variables for the two signal-side kaons,
- 1066 • number of kaons, tracks and distant tracks in ROE,
- 1067 • θ angle of the ROE momentum in CMS frame,
- 1068 • ξ_Z from [12]
- 1069 • Δz ,
- 1070 • m_{miss}^2 from Eq. (4.11),
- 1071 • $B \rightarrow D^*\ell\nu$ veto variables,

1072 where distant tracks are all tracks in ROE which satisfy the condition of $|d_0| >$
 1073 10.0 cm or $|z_0| > 20.0$ cm. The last entry, $B \rightarrow D^*\ell\nu$ veto variables, are a set of
 1074 variables where we partially reconstruct the D^* candidate 4-momentum via a linear
 1075 combination of the π_s^\pm 4-momentum in the $D^* \rightarrow D\pi_s^\pm$ decay. It helps discard the
 1076 most dominant $B \rightarrow D^*\ell\nu$ background. It is most efficient in the $B^0 \rightarrow D^{*-}\ell^+\nu$
 1077 decay, where D^{*-} further decays via $D^{*-} \rightarrow \bar{D}^0\pi_s^-$. Other decays do not contain a
 1078 charged π_s particle and are harder to reconstruct with good precision. This results
 1079 in larger suppression of the neutral $B\bar{B}$ background only. Figures 6.5 shows the veto
 1080 variable with a partial reconstruction of a charged π_s^\pm .

Figure 6.5: Distribution of m_{miss}^2 for partially reconstructed $B^0 \rightarrow D^{*-}\ell^+\nu$ decays, which serves as a veto.

1081 When the training is finished and the hyper-parameters of the classifier are opti-
 1082 mized, the classifier output, as shown in Figure 6.6 (left), can be used for background
 1083 suppression. B meson candidates from $B\bar{B}$ background are dominant at lower val-
 1084 ues, while candidates from $B\bar{B}$ events populate the region with higher values. Since

the differences between signal and background $B\bar{B}$ events are smaller than $B\bar{B}$ and $q\bar{q}$ events, the resulting classifier has a smaller separation power than in the previous section.

6.3.1 Boosting to Uniformity

The selection approach with standard classifiers is optimal for counting experiments, as it by construction produces the optimal selection for observing an excess of signal over background events. Today's BDT algorithms, which work in this way, produce non-uniform selection efficiencies and may, as a consequence, shape background distributions to look like signal. In order to minimize such behavior, it is possible to discard variables, which are correlated with the variable of interest (in our case ΔE and M_{BC}), from the training set. This, however, decreases the classifiers discriminating power. Another approach is to use a novel boosting method, uBoost, which is trained to optimize an integrated FOM under the constraint that the BDT selection efficiency for the desired class must be uniform. The uBoost algorithm balances the biases to produce the optimal uniform selection [13].

The training set used in this training is the same as described at the beginning of this chapter, along with the same set of training variables. It will be seen later that the standard BDT classifier shapes the background to look like signal mostly in the M_{BC} picture, therefore we train the uBDT classifier with a uniformity constraint in the M_{BC} variable for background candidates with the uBoost algorithm. The resulting classifier output is shown in Figure 6.6 (right). For this classifier, the separation power between signal and background seems worse, however, the shapes of backgrounds differ significantly, which greatly affects the performance of signal extraction.

Figure 6.6: $B\bar{B}$ suppression classifier output for signal and various types of background for the standard BDT classifier (left) and the uBDT classifier (right). B candidates from $B\bar{B}$ background events dominate the lower region, while signal and control candidates dominate in the upper region of the classifier output.

6.4 Selection Optimization

Instead of two separate $q\bar{q}$ and $B\bar{B}$ FOM optimizations, it is more efficient to do a simultaneous 2D FOM optimization, since the two classifiers are not completely uncorrelated. In the same manner, as before, FOM is optimized for perfectly reconstructed signal candidates in the signal window, after all the pre-cuts, signal categorization, and after cutting out the background resonances and the control decay. The FOM plot with the optimal point for both $B\bar{B}$ MVA classifiers is shown in Figure 6.7.

Figure 6.7: 2D FOM optimization of continuum suppression classifier and the standard BDT (left) and uBDT (right) $B\bar{B}$ suppression classifier.

We can compare signal and major background distributions of ΔE and M_{BC} after the 2D FOM optimization for both classifiers. Figure 6.8 shows the arbitrary (left) and normalized scale (right) for ΔE (top) and M_{BC} (bottom) for the final sample optimized with the standard BDT classifier, while Figure 6.9 shows similarly for the final sample optimized with uBDT classifier. We can see that there is considerably more background in the latter case, however, also shapes of background and signal distributions differ greatly, meaning there is less room for correlation. The biggest change seems to be in the shape of the M_{BC} distribution, where the background component is much more signal like in the final sample optimized with the standard BDT classifier than in the other case. Additionally, the shapes are more easily constrained in the latter case, since they are present in regions where no signal is expected. The total numbers of expected signal candidates and the signal-to-noise ratios for both classifiers are:

- Standard BDT: $N_{sig} = 176$, $N_{sig}/N_{bkg} = 4.83\%$,
- uBDT: $N_{sig} = 264$, $N_{sig}/N_{bkg} = 1.33\%$.

Due to the large difference in ΔE and M_{BC} shape, we will continue the analysis with the uBDT classifier, although the comparison between both methods will be shown for the final fit result in the next chapter.

Figure 6.8: Arbitrary (left) and normalized scale (right) for ΔE (top) and M_{BC} (bottom) for the final sample optimized with the standard BDT classifier.

Figure 6.9: Arbitrary (left) and normalized scale (right) for ΔE (top) and M_{BC} (bottom) for the final sample optimized with the uBDT classifier for $B\bar{B}$ suppression.

6.4.1 $B\bar{B}$ Background Composition and Lepton Veto

The majority of background candidates after the final selection is represented by candidates from $B\bar{B}$ events. In order to suppress this background even further, we need to take a look at its structure and recognize various contributions to this part of the background. Figure 6.10 shows ΔE and M_{BC} for the most significant contributions, along with m_{KK} . While most of the candidates come from events where all reconstructed charged particles in the signal decay do not come from one B meson, but both of them, these candidates are not so problematic, because their distribution is rather smooth and frequent in regions where we expect no signal. On the other hand, there are also contributions from B meson decays which produce more signal-like distributions. We will denote the first kind of background as $\Upsilon(4S)$ -matched and the second kind as the B -matched $B\bar{B}$ background. Fortunately, these decays are well known and well measured, so their yields can be constrained. Especially

1148 problematic is the double semileptonic decay $B \rightarrow \bar{D}^{(*)}\ell^+\nu$, $D^+ \rightarrow \bar{K}^-\ell^+\nu$, where
 1149 the secondary lepton is misidentified as a kaon. Even though the decay has two neu-
 1150 trinos, these events survive the m_{miss}^2 selection cut and produce peaks at the same
 1151 positions as signal distributions, while exhibiting only a slightly worse resolution.

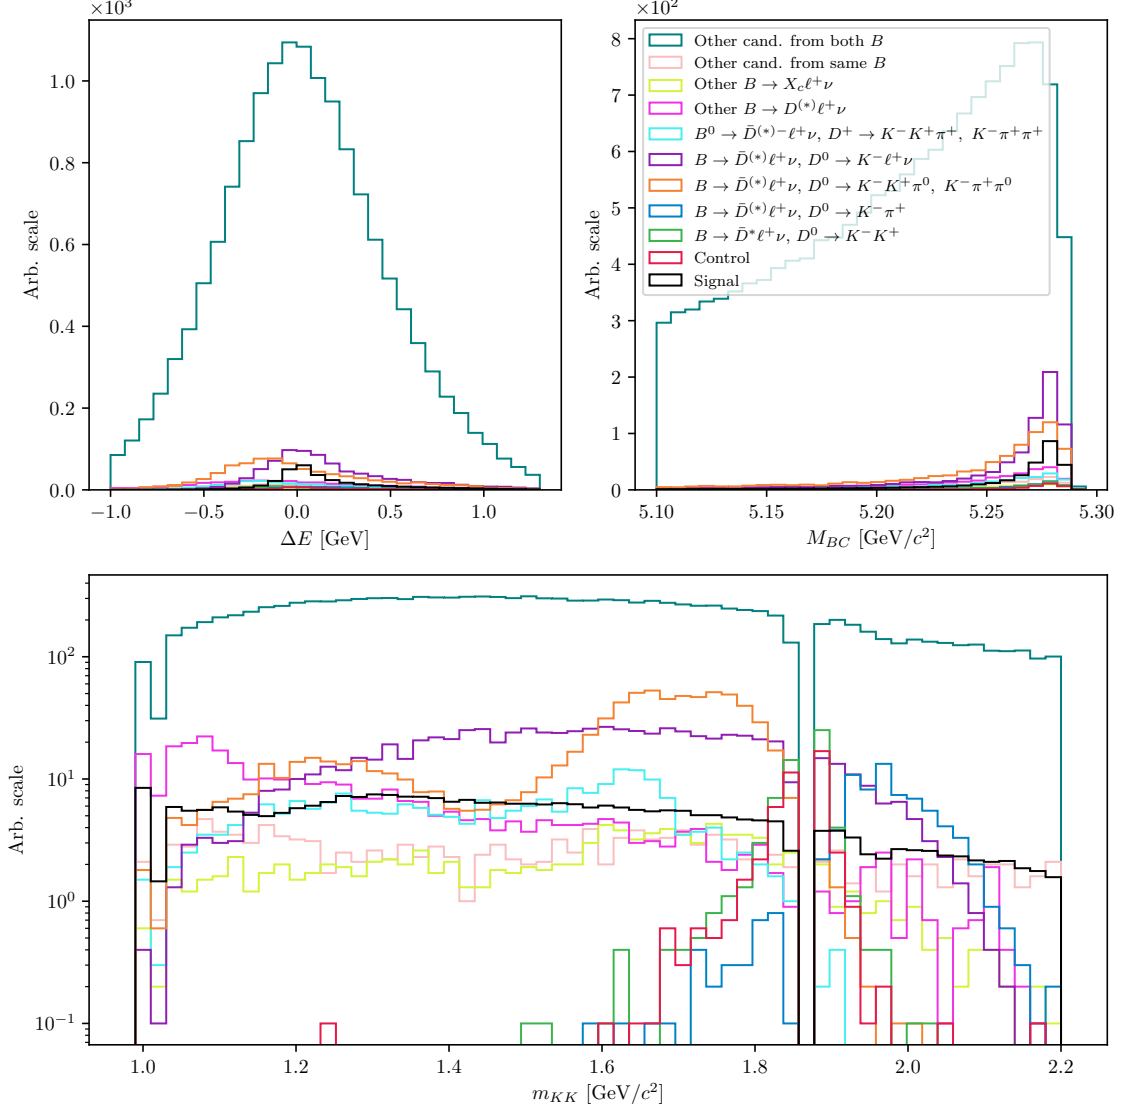

Figure 6.10: ΔE (left), M_{BC} (right) and m_{KK} (bottom) for major contributions to the $B\bar{B}$ background in the signal cut region. $\Upsilon(4S)$ -matched backgrounds represents the majority, but has a smooth and wide background, which has a distinguishable shape from signal. B -matched contributions show a peak in M_{BC} and sometimes in ΔE , but can be constrained using existing measurements.

1152 In order to suppress these candidates, a lepton veto can be applied to both kaons,
 1153 stating that neither of the kaons should exhibit lepton-like properties. On the can-
 1154 didates passing the final selection, we optimize the eID and μID PID cuts, where
 1155 S and B in Eq. 4.1 are represented by perfect signal candidates and by background

candidates, respectively, whereas in the latter case a lepton has been misidentified as a kaon. 2D FOM plots for both kaons are shown in Figure 6.11, where it can be seen that in the majority of the cases, an electron is misidentified as the kaon with the opposite charge to the B meson. With the optimal cuts of

- K_0 : $eID < 0.7$,
- K_1 : $eID < 0.1$, $\mu ID < 0.8$,

we reject 77.5% of candidates from the double semileptonic decays, while efficiency loss of signal and other types of $B\bar{B}$ background is about 5 – 6%. The $B\bar{B}$ background after the lepton veto cuts is shown in Figure 6.12 for the signal cut region, and in Figure 6.13 for the control cut region.

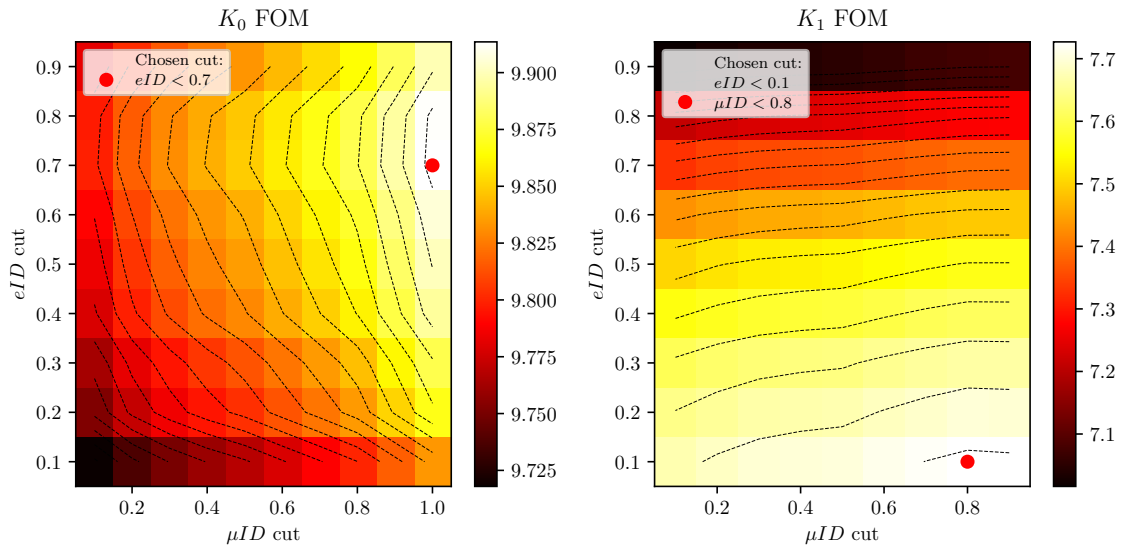

Figure 6.11: 2D FOM for optimal eID and μID cuts on same-sign (left) and opposite-sign (right) kaons with respect to the B meson charge. For double semileptonic background component, in most cases an electron is misidentified as the opposite-sign kaon in the reconstruction chain.

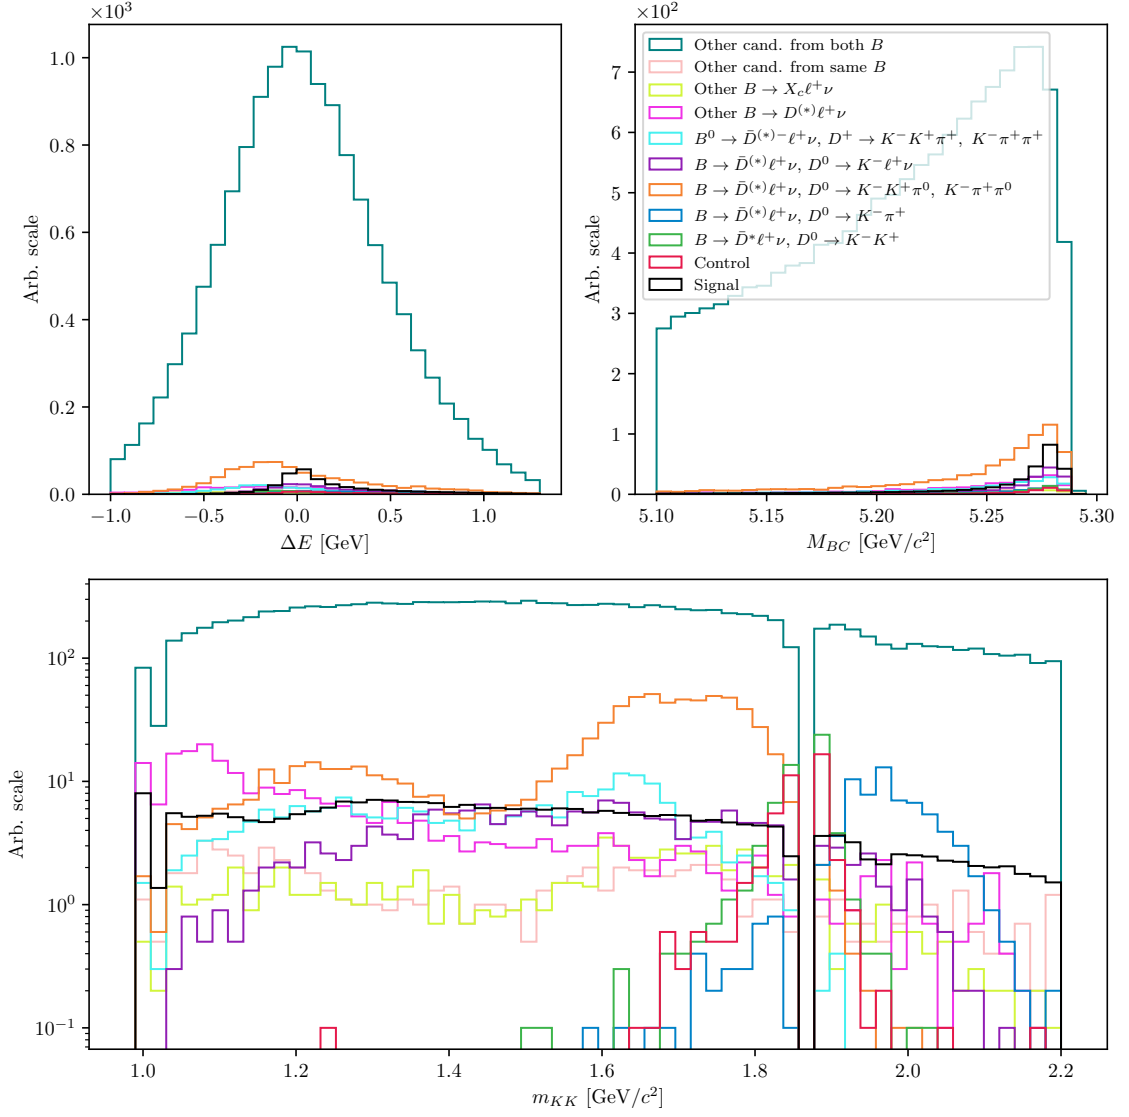

Figure 6.12: ΔE (left), M_{BC} (right) and m_{KK} (bottom) for major contributions to the $B\bar{B}$ background in the signal cut region after the lepton veto. The double semileptonic background component is suppressed by a factor of 4 – 5.

Figure 6.13: ΔE (left), M_{BC} (right) and m_{KK} (bottom) for major contributions to the $B\bar{B}$ background in the control cut region after the lepton veto. The major component in this case are other $B \rightarrow D^* \ell + \nu, D \rightarrow K^+ K^-$ decays, besides the control decay.

1166 6.5 Data and MC Agreement

1167 With the final selection in place, we can check the data and MC agreement by
 1168 checking the control decay region in on- and off- resonance data. Off-resonance
 1169 samples provide the ability to check the agreement of the $q\bar{q}$ background component,
 1170 while on-resonance samples can be used to check the validity of the control MC
 1171 sample and, consequentially, the signal MC sample.

6.5.1 Off-resonance Data

The off-resonance data were collected at 60 MeV below the $\Upsilon(4S)$ resonance peak energy in order to determine the non- $B\bar{B}$ background. It, therefore, offers a direct view of the $q\bar{q}$ background data sample, which we can compare to the off-resonance MC sample. Figure 6.14 shows ΔE , M_{BC} and the $q\bar{q}$ classifier output, $BDT_{q\bar{q}}$, for off-resonance data and stacked MC in the control region, before any MVA cuts, where the MC sample was scaled down by a factor of 6, due to 6 streams of MC. These figures do not show a fit to data, but merely an overlay of data and stacked MC distributions, and show good data and MC agreement of the off-resonance sample already before the fit. More importantly than the normalization, the shape of data and MC also seems to be the same, so further corrections of ΔE and M_{BC} on MC are not necessary. This is also consistent by the flatness of the ratio function for ΔE and M_{BC} , shown in the same Figure. There seems to be a difference in the classifier performance for the continuum background suppression on data and MC. This leads to further differences between data and MC in the $q\bar{q}$ sample after the classifier cut, but we estimate that these differences are negligible, since a relatively small amount of continuum background passes the selection, compared to other background types.

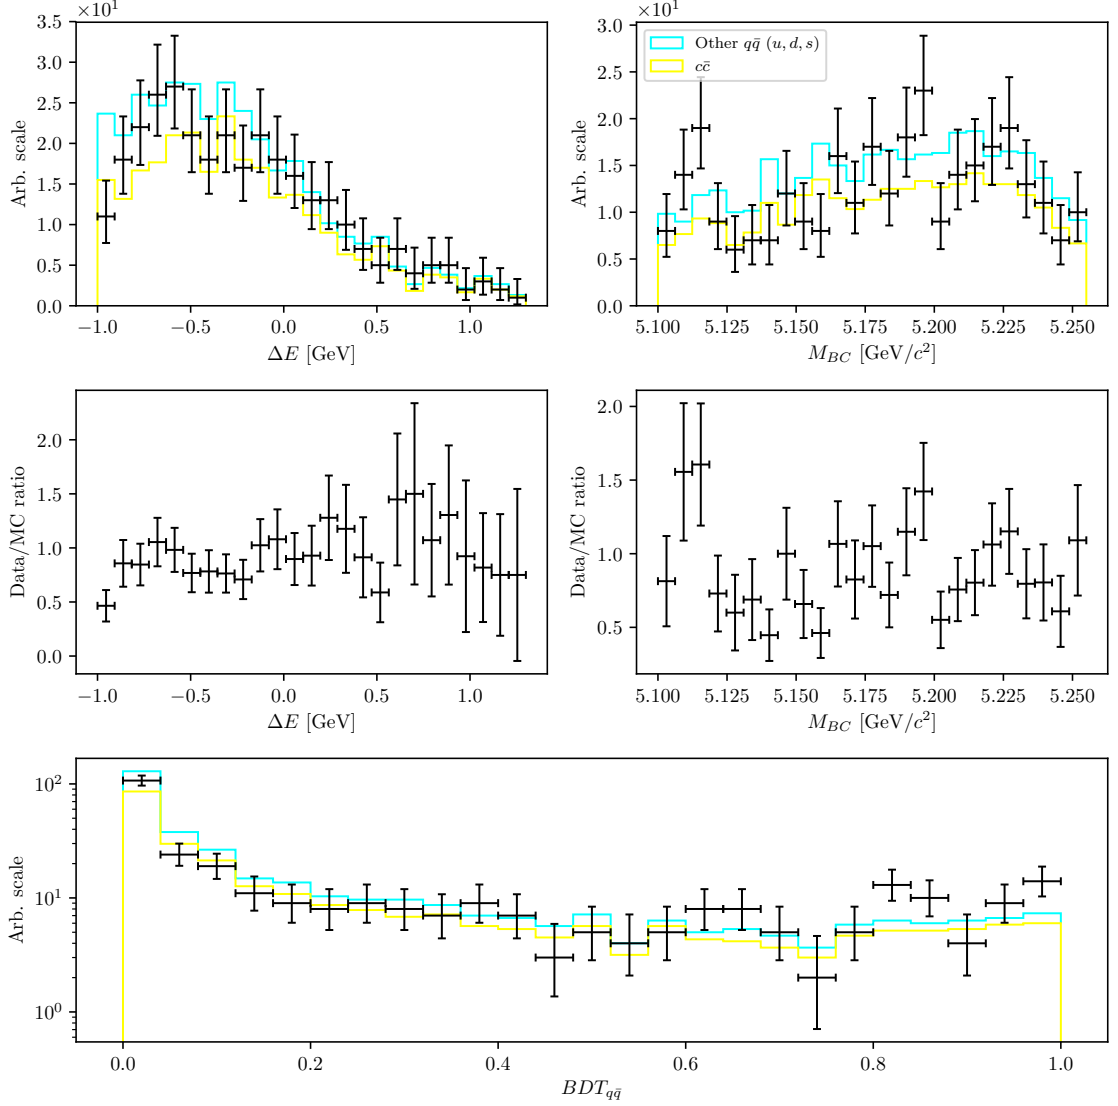

Figure 6.14: ΔE (left), M_{BC} (right) and the $q\bar{q}$ classifier output (bottom), for off-resonance data and MC in the control region before any MVA cuts.

6.5.2 On-resonance Data

We can repeat the check on on-resonance data. Figure 6.15 shows ΔE , M_{BC} and $BDT_{q\bar{q}}$, where one can see inconsistencies between data and stacked MC on the lower spectrum, where continuum background is dominant. These figures again do not show the fit, but merely an overlay of data to the stacked MC distributions, where we see that the MC is over-estimated in the lower region of the continuum suppression MVA output, most likely due to additional disagreements from other sources. On the other hand, data and MC seem to agree well in the upper part of the spectrum, where $B\bar{B}$ events are dominant. Overall, data and MC seem to agree well already off-the-shelf after all the pre-cuts and without any corrections. This means that the modeling of this MC sample is very precise in this particular region of data and that there are no significant differences between data and MC for the control sample and the signal sample.

Figure 6.15: ΔE (left), M_{BC} (right) and the $q\bar{q}$ classifier output (bottom), for on-resonance data and MC in the control region before any MVA cuts.

Chapter 7

Signal Extraction

In this chapter, the procedure for signal yield extraction is presented. We use the framework of `RooFit` [14] where we define 2D histogram templates in ΔE and M_{BC} , based on MC, for signal and several types of background. Using these templates, the independent full sample is fitted with the binned extended maximum likelihood (ML) fit, so that the individual template ratios and their sum describe the fitted sample as best as possible. In particle physics we are often dealing with low numbers of events and need to account for the Poisson nature of the data, therefore we use the likelihood fit, since it takes the Poisson errors into account, unlike the χ^2 fit, where the errors are assumed to be Gaussian. In this procedure, we attempt to find the parameter values that maximize the likelihood function, given the observations.

If $P(n|\vec{\alpha})$ is the probability of measuring n candidates, where $\vec{\alpha}$ is a set of parameters on which P depends, we can define the likelihood function L for a series of such measurements (i.e., bins in histogram) n_i based on Poisson statistics as

$$L(\vec{\alpha}) = \prod_{i=1} P(n_i|\vec{\alpha}) = \prod_{i=1} \frac{\mu_i^{n_i} e^{-\mu_i}}{n_i!}, \quad (7.1)$$

where μ_i is the expected value for each measurement. It is also common to search for the minimum of the negative value of $\ln L$, or negative log-likelihood (NLL), as

$$\mathcal{L}(\vec{\alpha}) = -\ln L(\vec{\alpha}) = -\sum_i \ln \left(\frac{\mu_i^{n_i} e^{-\mu_i}}{n_i!} \right) = \sum_i \ln(n_i!) + \mu_i - n_i \ln(\mu_i). \quad (7.2)$$

Maximizing L or minimizing \mathcal{L} gives us a maximum likelihood estimate of the set of parameters $\vec{\alpha}_{ML}$ which best describe the observed data.

The ML method provides a method to estimate the fit uncertainty. This is especially useful if the log-likelihood has a non-parabolic shape, which leads to asymmetric errors. We calculate the errors using the `MINOS` algorithm from the `MINUIT` package [15], which is implemented in `RooFit`. The algorithm follows the log-likelihood function out of the minimum to find the appropriate intervals of confidence for each parameter, taking the parameter correlations into account.

To estimate the goodness of the likelihood fit, one option is to generate toy MC experiments and obtain the expected log-likelihood distribution. Likelihood fits, however, also offer another way to test the goodness of fit via the likelihood ratio (LR), where we compare the likelihood obtained under the ML parameters $\vec{\alpha}_{ML}$, to the likelihood obtained under the null hypothesis parameters $\vec{\alpha}_{H_0}$. This determines how likely the data is under one model than the other. We define the LR test as

$$\lambda = -2 \ln \left(\frac{L(\vec{\alpha}_{ML})}{L(\vec{\alpha}_{H_0})} \right) = -2 [\ln L(\vec{\alpha}_{ML}) - L(\vec{\alpha}_{H_0})] \sim \chi_q^2, \quad (7.3)$$

which asymptotically behaves as the χ_q^2 distribution with $q = m - n$ degrees of freedom, where m and n are degrees of freedom of $L(\vec{\alpha}_{ML})$ and $L(\vec{\alpha}_{H_0})$, respectively. In particle physics we usually study a specific decay and try to perform measurements of the signal yield, so the null hypothesis in this case is that we expect to observe no signal. This means that for the null hypothesis we fix the expected signal yield parameter to zero, while leaving the other parameters of $\vec{\alpha}_{H_0}$ the same as in $\vec{\alpha}_{ML}$, which results in $n = m - 1$ degrees of freedom and in their difference $q = m - n = 1$. For such a simple LR test of a single parameter the LR test then follows the χ^2 distribution with 1 degree of freedom. In this case we can define the fit significance from the χ^2 value in units of σ as

$$\text{Significance} = \sqrt{\lambda} = \sqrt{\chi^2}. \quad (7.4)$$

7.1 Fit Setup

We perform 10 fits to each stream of MC, where 9 streams were used for the creation of the templates and the remaining stream was used as fitted data. When fitting real data, all available MC was used for creating the templates. The full signal MC sample was used for the signal template definition in case of MC as well as data fits. The signal part of the `ulnu` sample was not used in template construction, it was only used as a part of the fitted sample.

The same MC samples are used for template construction as described in chapter 2,

- signal MC,
- 10 streams of `charged` and `mixed` $B\bar{B}$ background,
- 6 streams of $c\bar{c}$ (`charm`) and other $q\bar{q}$ (`uds`) background,
- `ulnu` sample, corresponding to $20\times$ integrated luminosity of the full Belle dataset,
- `rare` sample, corresponding to $50\times$ integrated luminosity of the full Belle dataset.

7.1.1 Control Fit

$B\bar{B}$ background composition in control region is shown in Figure 6.13. Due to the strict cut of the m_{KK} around the D^0 mass window, most of the decays with a D^0 proceed via $D^0 \rightarrow K^+K^-$ decay. In this case, the following fit templates are chosen

- signal template,
- $q\bar{q}$ template,
- C_0 : $B^+ \rightarrow \bar{D}^0\ell^+\nu$, $D^0 \rightarrow K^-K^+$ (control decay),
- C_1 : $B \rightarrow \bar{D}^*\ell^+\nu$, $D^0 \rightarrow K^-K^+$,
- other $B\bar{B}$ BKG template.

1268 In control fits, all template shapes are fixed and the yields of all templates are floated,
 1269 except for the signal template, which is expected to be very close to zero and is fixed
 1270 to the expected MC yield. Additionally, since the C_0 and C_1 decays are well known
 1271 and measured, we make use of this fact in the form of a ratio N_{C_1}/N_{C_0} , which is
 1272 fixed to the MC value in case of the MC fit and constrained to the measured value
 1273 in case of fits to real data. The ratio is implemented based on the decay channels
 1274 shown in Table 7.1 and is defined as

$$r_1 = \frac{\left(\sum_j N_{1j} \times \rho_{1j}\right)}{N_{00} \times \rho_{00}}, \quad (7.5)$$

1275 where j runs over all channels in the category C_1 and where ρ_{ij} is the branching
 1276 ratio correction factor for the specific channel N_{ij} , which incorporates information
 1277 from world measurements. It is defined as

$$\rho = \frac{\mathcal{B}^{PDG}}{\mathcal{B}^{GEN}}, \quad (7.6)$$

1278 where \mathcal{B}^{PDG} is the measured branching ratio and \mathcal{B}^{GEN} is the branching ratio value
 1279 used in MC generation. The branching ratio correction factor has been implemented
 1280 due to differences between measured and MC branching ratio values. Each branch-
 1281 ing ratio measurement serves as a constraint used in the fit. All branching ratio
 1282 constraints in the control fit are shown in Table 7.2. The measured values are
 1283 cited only for the B^0 decay mode, where isospin symmetry has been assumed. The
 1284 corresponding B^+ branching ratios can be calculated as

$$\mathcal{B}(B^+) = \mathcal{B}(B^0) \times \tau_{B^+/B^0}, \quad (7.7)$$

1285 where τ_{B^+/B^0} is the ratio of B -meson decay times, which is measured to be [4]

$$\tau_{B^+/B^0} = 1.076 \pm 0.004. \quad (7.8)$$

Category	Channel	B Decay Mode	D Decay Mode	N_{MC}
C_0	N_{00}	$B^+ \rightarrow \bar{D}^0 \ell^+ \nu$	$D^0 \rightarrow K^- K^+$	1182 ± 34
C_1	N_{10}	$B^+ \rightarrow \bar{D}^{*0} \ell^+ \nu$	$D^0 \rightarrow K^- K^+$	1455 ± 38
	N_{11}	$B^0 \rightarrow D^{*-} \ell^+ \nu$	$D^0 \rightarrow K^- K^+$	186 ± 16

Table 7.1: Well defined decay channels used for constraining the control fits.

1286 In case of MC fits, the fitted sample is also generated with MC, so $\mathcal{B}_i^{PDG} = \mathcal{B}_i^{GEN}$
 1287 and Eq. (7.5) simplifies to a simple MC yield ratio. On fits to real data, expected MC
 1288 yields and branching ratio measurements are implemented as independent Gaussian
 1289 constraints in order to properly account for correlations in Eq. (7.5).

ID	Decay	\mathcal{B}_{GEN}	\mathcal{B}_{PDG}	ρ	Ref.
0	$B^0 \rightarrow D^- \ell^+ \nu$	2.13×10^{-2}	$(2.13 \pm 0.09) \times 10^{-2}$	1.00 ± 0.04	[4]
1	$B^0 \rightarrow D^{*-} \ell^+ \nu$	5.33×10^{-2}	$(4.88 \pm 0.11) \times 10^{-2}$	0.92 ± 0.02	
2	$B^+ \rightarrow \bar{D}^0 \ell^+ \nu$	2.31×10^{-2}	$(2.29 \pm 0.10) \times 10^{-2}$	0.99 ± 0.04	[calc.]
3	$B^+ \rightarrow \bar{D}^{*0} \ell^+ \nu$	5.79×10^{-2}	$(5.25 \pm 0.12) \times 10^{-2}$	0.91 ± 0.02	
4	$D^0 \rightarrow K^- K^+$	3.90×10^{-3}	$(3.97 \pm 0.07) \times 10^{-3}$	1.02 ± 0.02	[16]

Table 7.2: MC and measured values of branching ratios along with the calculated correction factors used for constraining the control fit.

Smearing and Offset Parameters

With simulated data, we are able to perform detailed studies prior to looking at the measured data. However, simulated data often does not describe real data perfectly. Out of variables ΔE and M_{BC} , ΔE is especially prone to a lack of precision in energy measurements. This can introduce either overestimation of resolution on MC as well as a possible shift in the measured energy in either direction. Due to this fact, we introduce a modification of the ΔE variable by applying a smearing factor and an offset. These are applied by simple transformations of

$$f_{\text{offset}} : x \mapsto x + a, \quad (7.9)$$

$$f_{\text{smearing}} : x \mapsto \frac{1}{\sqrt{2\pi}\sigma^2} e^{-\frac{(x-\mu)^2}{2\sigma^2}}, \quad (7.10)$$

where x goes over all entries in the ΔE distribution, a is the energy offset and f_{smearing} corresponds to the normal distribution with mean μ and standard deviation σ . In case of the M_{BC} variable the mentioned effects are not as prominent, so the smearing and offset for the latter variable are omitted.

The following parameter phase space is scanned in order to determine the best parameter values

- smearing factor in range $[0.0, 0.08]$ GeV in steps of 8×10^{-3} ,
- offset in range $[0.0, 0.003]$ GeV in steps of 1.5×10^{-4} ,

where for each parameter pair the likelihood ratio test is performed to estimate the goodness of the fit. Figure 7.1 shows the contour plot of the likelihood ratio λ , as defined in Eq. (7.3), for 2 d.o.f., for MC (left) and data (right). The scan over MC serves the purpose of a consistency check, where we expect the best fit to occur in the phase space where neither smearing nor offset are applied. In the case of data, we see that we obtain a better fit by introducing some level of smearing and offset. In both cases, the two parameters have shown no sign of significant correlation, so we treat them independently. The likelihood ratio test allows us to estimate the parameter values in the 1σ confidence interval, where we obtain the optimal parameter set

- Smearing: 40^{+15}_{-17} MeV,
- Offset: $6^{+4.6}_{-6}$ MeV.

1311 We apply this transformation to our MC samples in all cases when fitting real data.

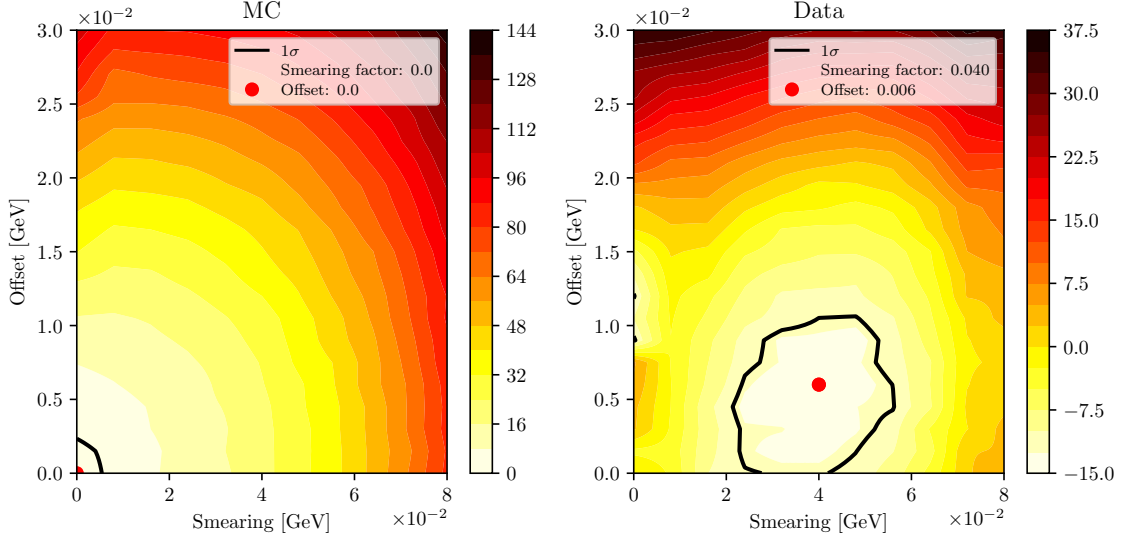

Figure 7.1: Likelihood ratio test of an additional smearing and offset parameter to MC (left) and data (right).

1312 7.1.2 Signal Fit

1313 The motivation for the choice of signal fit templates comes from Figure 6.12. The
1314 following histogram templates were defined

- 1315 • signal template,
- 1316 • $q\bar{q}$ template,
- 1317 • a series of well defined templates from $B\bar{B}$ background:
 - 1318 – C_0 : $B^+ \rightarrow \bar{D}^0 \ell^+ \nu$, $D^0 \rightarrow K^- K^+$ (control decay),
 - 1319 – C_1 : $B \rightarrow \bar{D}^* \ell^+ \nu$, $D^0 \rightarrow K^- K^+$,
 - 1320 – C_2 : $B \rightarrow \bar{D}^{(*)} \ell^+ \nu$, $D^0 \rightarrow K^- \pi^+$,
 - 1321 – C_3 : $B \rightarrow \bar{D}^{(*)} \ell^+ \nu$, $D^0 \rightarrow K^- K^+ \pi^0$, $K^- \pi^+ \pi^0$,
 - 1322 – C_4 : $B \rightarrow \bar{D}^{(*)} \ell^+ \nu$, $D^0 \rightarrow K^- \ell^+ \nu$,
 - 1323 – C_5 : $B^0 \rightarrow D^{(*)-} \ell^+ \nu$, $D^+ \rightarrow K^- K^+ \pi^+$, $K^- \pi^+ \pi^+$,
 - 1324 – C_6 : other $B \rightarrow \bar{D}^{(*)} \ell^+ \nu$ decays,
- 1325 • remaining $B\bar{B}$ background template.

1326 As mentioned in chapter 6, the majority of the background comes from $B\bar{B}$ events.
1327 Various processes (C_0 to C_6) contribute to this background which are well known and
1328 measured, so we make use of these measurements by fixing their yields in MC fits and
1329 appropriately constraining them in real data fits. The remaining $B\bar{B}$ background is
1330 merged into a single template. In this case, the shape of all templates is fixed as well,
1331 while the yields are floated for all templates except for the constrained background

1332 templates. The yield constraints are based on the channels shown in Table 7.3 and
 1333 defined for each template category as

$$Y_i = \eta_{\text{norm.}} \times \frac{\left(\sum_j N_{ij} \times \rho_{ij}\right)}{\rho_{00}}, \quad (7.11)$$

1334 where j runs over all channels in the category C_i and where ρ_{ij} is defined in Eq.
 1335 (7.6). The first factor, $\eta_{\text{norm.}}$, serves as a normalization factor in order to scale the
 1336 number of generated $B\bar{B}$ events to the number of $B\bar{B}$ events in measured data. We
 1337 define it as

$$\eta_{\text{norm.}} = \frac{N_{\text{control}}^D}{N_{\text{control}}^{MC}}, \quad (7.12)$$

1338 where N_{control}^D and N_{control}^{MC} are control yields in the control fit for data and MC,
 1339 respectively.

1340 In addition to branching ratio constraints in Table 7.2, further constraints are
 1341 defined in Table 7.4 due to more decay channels. In case of the category C_6 , we
 1342 have no firm handle on the D meson decay, therefore no correction for this branching
 1343 ratio can be introduced, so we set a correction factor of 1 with a 100% error for the D
 1344 meson decay branching ratio. As most of the correction factors used for constraints
 1345 have deviations (including the errors) from nominal values well below 100% this
 1346 value is very conservative.

Category	Channel	B Decay Mode	D Decay Mode	Expected MC Yield
C_0	N_{00}	$B^+ \rightarrow \bar{D}^0 \ell^+ \nu$	$D^0 \rightarrow K^- K^+$	44 ± 7
C_1	N_{10}	$B^+ \rightarrow \bar{D}^{*0} \ell^+ \nu$	$D^0 \rightarrow K^- K^+$	53 ± 7
	N_{11}	$B^0 \rightarrow D^{*-} \ell^+ \nu$	$D^0 \rightarrow K^- K^+$	6 ± 2
C_2	N_{20}	$B^+ \rightarrow \bar{D}^0 \ell^+ \nu$	$D^0 \rightarrow K^- \pi^+$	23 ± 5
	N_{21}	$B^+ \rightarrow \bar{D}^{*0} \ell^+ \nu$	$D^0 \rightarrow K^- \pi^+$	41 ± 6
	N_{22}	$B^0 \rightarrow D^{*-} \ell^+ \nu$	$D^0 \rightarrow K^- \pi^+$	6 ± 2

11	$D^+ \rightarrow K^- \pi^+ \pi^+$	9.51×10^{-2}	$(8.98 \pm 0.28) \times 10^{-2}$	0.94 ± 0.03	

Table 7.4: Additional MC and measured values of D meson branching ratios along with the calculated correction factors used for constraining the signal fit.

7.2 Adaptive Binning Algorithm

The fit templates contain areas of low statistics, which are populated with bins with zero content. This is a direct consequence of having a finite MC sample and represent a liability in ML fits. Due to low statistics in the edge regions, the locations of these empty bins can vary for the templates and the fitted sample. A problem occurs if all templates have an empty bin where the fitted sample does not. In the scope of ML fits, this effectively means that there are entries in bins where the probability of having them is 0. We will call such bins *problematic* because in these cases the fit does not converge.

The ideal solution for this problem would be to increase the MC statistics. Since this is not an option, we pursue other solutions, such as decreasing the number of bins. While this solves the problem, the drawback of it is a decrease in the template resolution in densely populated regions, where good resolution is most needed. The optimal solution here seems to be a choice of variable bins, with fine binning in the densely populated regions and larger bins in the regions with low statistics.

We have devised an algorithm, which compares the templates and the fitted sample, and defines a variable binning so that there are no more problematic bins in the end. Figure 7.2 shows an example of how the procedure works. The algorithm takes an argument for the initial number of uniform bins in each dimension and does the following

1. define uniform binning in both dimensions with the provided argument,
2. create a 2D histogram from MC templates with expected yields,
3. define an *optimal* region, where most of the 2D integral is contained and where all bins have a non-zero content (this region does not change throughout the process),
4. compare the histograms for the expected and the fitted sample, find the problematic bins,
5. loop until all problematic bins disappear
 - a) find the problematic bin, which is nearest to the maximum bin,
 - b) change the binning from N to $N - 1$ from that bin and in the direction away from the maximum bin.

Figure 7.2: Steps taken in the adaptive binning algorithm. Left image shows the initial 2D histogram with the defined optimal region and the problematic bins, the right image shows the final binning with the unchanged optimal region, while the problematic bins are gone due to the new binning choice.

1378 An additional problem occurs in the plotting of the fitted templates and the sample
 1379 with variable binning. It would seem that RooFit does not take the bin widths into
 1380 account when plotting, while everything works as expected for the fit itself. This
 1381 was bypassed by extracting the fitted yields and applying them to templates and
 1382 samples with uniform binning, which were then used for drawing.

1383 7.3 Toy MC Experiments

1384 For the chosen final selection and fit procedure, toy MC pseudo-experiments were
 1385 performed in order to confirm the behavior of the fit setup. The fit behavior is also
 1386 checked as a function of the signal yield in the form of a linearity test. A detailed
 1387 description of toy MC experiments is written in this section.

1388 With toy MC experiments in this section, we study the yields, errors and the pulls
 1389 of the signal fit by generating our own pseudo-datasets, according to the MC. This
 1390 significantly reduces the time we would need to produce the datasets in the standard
 1391 way, while still reliably describing the underlying physics behind the pseudo-dataset.
 1392 All available MC was used for pseudo-dataset generation as well as creating tem-
 1393 plates.

1394 7.3.1 Pseudo-Experiment: Expected Signal Yield

1395 We constructed 3×10^3 pseudo-datasets, where each dataset was generated with the
 1396 expected amount of each template category, distributed according to the Poisson
 1397 distribution. All fits were performed with the optimal initial uniform binning of
 1398 19×19 bins in ΔE and M_{BC} .

Figure 7.3 shows distributions of the fit yields, errors and the pull distribution of all pseudo-fits. The fits seem to be under control, although there is a slight bias present in the negative direction, which can also be seen in the pull distribution plot. The latter follows a normal distribution with a mean of (-0.11 ± 0.02) and standard deviation of (1.01 ± 0.01) . The mean (\bar{X}) and the standard deviation (S) were calculated in the usual way, while their errors $\sigma_{\bar{X}}$ and σ_S were calculated as [17]

$$\sigma_{\bar{X}} = \frac{S}{\sqrt{N}}, \quad \sigma_S = \frac{S}{\sqrt{2(N-1)}}, \quad (7.13)$$

where N is the number of performed measurements. It seems that there is a small bias present in the pseudo-fits. A decision has been made to put this difference as one of the contributions to the overall systematic uncertainty.

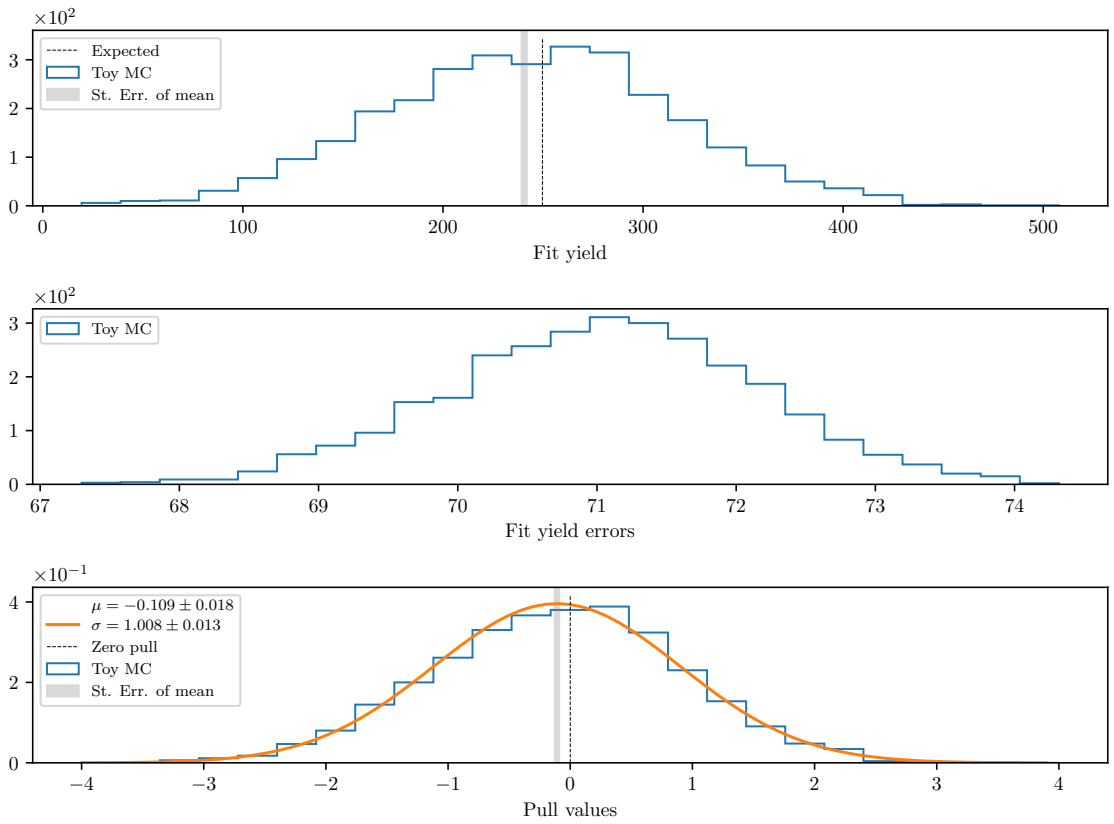

Figure 7.3: Toy MC fits of pseudo-data showing the fit yield (top), fit errors (center) and the pull distribution of the fits (bottom).

7.3.2 Pseudo-Experiment: Linearity Test

Linearity test is used for determining the sensitivity of the fit to the amount of signal in the fitted sample. Since this is the first measurement of this decay channel, MC modeling is not reliable and could be very different from reality, so we need to perform this test in order to determine our sensitivity to smaller, as well as larger amounts of expected signal.

The pseudo-datasets are generated in the same way as in the previous subsection, with the exception of signal, which is generated in various amounts. 50 steps from

1416 [0.1, 10] in the logarithmic scale are taken for fractions of signal amount and for
 1417 each fraction we generate 500 pseudo-datasets according to Poisson statistics.

1418 Figure 7.4 shows the difference between mean fit yield and the expected yield,
 1419 mean pull and the mean significance at each signal fraction value. The expected
 1420 MC result lies at the fraction value $10^0 = 1$. The plots show a small bias with
 1421 respect to the expected signal yield, while the pulls seem to be described by the
 1422 normal distributions throughout the fraction range with a slight offset, which will
 1423 be incorporated as a contribution to the overall systematic uncertainty. At expected
 1424 value, we are at about 3.58σ significance.

Figure 7.4: Mean fit yield and expected yield difference (top), mean pull (center) and mean significance (bottom) as a function of signal fraction.

1425 7.4 Fit Results

1426 In this section, we present the first results of signal and control fits on MC as well
 1427 as data, along with the control decay branching ratio measurement. We also show
 1428 results of the signal fit on MC and data.

1429 7.4.1 Signal MC Fit Results

1430 With the signal fit setup described in section 7.1.2, we proceed to fit the 10 streams
 1431 of MC. To compare both methods of $B\bar{B}$ bar suppression, two different samples
 1432 were prepared and used in the fit. Since the choice of initial uniform binning is not

obvious, we perform fits to all streams of MC for each initial binning choice in the range $N \times N$, $N \in [4,30]$. Figure 7.5 shows the expected yield differences, pulls and fit significances for both final samples for each binning case. The difference between fitted and expected signal yield should be equal to 0 to ensure no bias is present in the fit, while the average pull distribution for each bin case should have a central value at 0, with a width of 1. It can be seen from the plots that this is not exactly the case, as a slight offset is present in the other direction as in the case of the pseudo-experiments. This difference is also accounted for as a contribution to the overall systematic uncertainty. The pull distribution seems to be closer to the normal distribution for the case of the uBDT classifier, as well as the fit significance appears to be larger by approximately 1σ , so we conclude that the uBDT classifier fit setup outperforms the standard BDT fit setup, which determines our choice of the final selection. The binning in ΔE and M_{BC} is chosen at the plateau of the significance, where no significant bias is present and is somewhere in the region of 20 bins in each dimension.

Figure 7.5: Fitted yield and expected yield difference (top), pulls (center) and fit significance (bottom) as a function of binning in ΔE and M_{BC} for the final sample, optimized with the standard BDT classifier (blue) and the uBDT classifier (orange).

For the chosen binning of 19×19 in ΔE and M_{BC} we perform the 10 stream MC fits, where an average stream fit is shown in Figure 7.6, while all fit results are shown in Figure 7.7. All stream fit results were fitted with a 0th-degree polynomial. The global result seems to describe the expected value in a precise manner, with

1452 the bias much smaller than the average statistical error. The normalized χ^2 value
 1453 with $10 - 1 = 9$ degrees of freedom of the global fit is $\chi^2_9 = 0.98$, while the average
 1454 significance of the fits is around 3.56σ .

Figure 7.6: An example fit to one stream of MC. Left column shows the M_{BC} and the right column shows the ΔE distribution of the full fitted sample in the full fit region (top) and the signal region (bottom).

Figure 7.7: Fits to all 10 streams of MC and the global fit with a zero degree polynomial. The red line shows the mean value of the global fit and the gray band shows the 1σ confidence interval.

7.4.2 Control Fit Result

With the control fit setup described in section 7.1.1, we proceed to fit the control sample after the final selection for 10 streams of MC and 1 stream of data. An average MC stream fit is shown in Figure 7.8 for MC and Figure 7.9 for data, while all fit results are shown in Figure 7.10, where all streams of MC are fitted with a 0th degree polynomial. The control fit results for split and joined lepton modes are shown in Table 7.5.

	N^{MC}	N^{data}
$\ell = e \text{ or } \mu$	1180 ± 11	1192 ± 44
$\ell = e$	590 ± 9	588 ± 28
$\ell = \mu$	591 ± 7	610 ± 30

Table 7.5: Control sample fit results for MC and data for various lepton final state modes.

Figure 7.9: Control fit result on real data. Left column shows the M_{BC} and the right column shows the ΔE distribution in the full fit window (top) and the signal window (bottom).

Figure 7.10: Control fit to data and to all 10 streams of MC. The red line shows the mean value of the global MC fit with a 0th degree polynomial. The gray band shows the 1σ confidence interval around the global MC fit.

1462 Branching Ratio Measurement for Control Decay

1463 After acquiring the fit results on MC and data, we are able to determine the branch-
 1464 ing ratio of the control decay, which is defined as

$$\mathcal{B}_{\text{control}}^{MC} = \frac{N_{\text{control}}^{MC} \times \epsilon_{MC}}{2N_{B\bar{B}}^{MC}}, \quad (7.14)$$

$$\mathcal{B}_{\text{control}} = \frac{N_{\text{control}} \times \epsilon_{MC} \times \rho_{PID}}{2N_{B\bar{B}}}, \quad (7.15)$$

1465 where N_{control}^{MC} and N_{control} are yields of the control fit on MC and data, ϵ_{MC} is the
 1466 MC efficiency of the control sample, ρ_{PID} the PID correction factor, and $N_{B\bar{B}}^{MC}$ and
 1467 $N_{B\bar{B}}$ are the numbers of $B\bar{B}$ meson pairs on MC and data, respectively. The factor
 1468 of 2 in the denominator comes from the fact that there are 2 B mesons in each B
 1469 meson pair ($\times 1/2$), where only about 50% of the B meson pairs are charged B^+B^-
 1470 meson pairs ($\times 2$), and from the fact that we are interested in the branching ratio
 1471 to the lepton final state of either e or μ , and not their sum ($\times 1/2$).

The control sample efficiency was determined on a separate signal MC sample of the control decay, where we generated 5×10^6 $B^+\bar{B}^-$ pairs, with one B always decaying via $B^+ \rightarrow \bar{D}^0 \ell^+ \nu$, $D^0 \rightarrow K^+ K^-$. After applying the final selection, the full and split efficiencies with regard to the lepton final state were determined to be

$$\begin{aligned} \epsilon_{MC} &= (8.89 \pm 0.04) \times 10^{-3}, \\ \epsilon_{MC}^e &= (4.40 \pm 0.03) \times 10^{-3}, \\ \epsilon_{MC}^\mu &= (4.49 \pm 0.03) \times 10^{-3}, \end{aligned}$$

where the efficiency error was estimated based on a formula from [18].

$$\epsilon_{MC} = \frac{1}{N} \sqrt{n(1 - \frac{n}{N})},$$

1472 where n is a subset of the full set N .

The PID correction factor is obtained by taking into account the known PID efficiency differences between data and MC. It is described in detail in section 8.1.1 and is determined to be

$$\rho_{PID} = 0.99 \pm 0.02$$

1473 for the e and μ mode, as well as both of them together.

The number of $B\bar{B}$ meson pairs can be counted on MC and has been measured for data by the collaboration. The values are

$$\begin{aligned} N_{B\bar{B}}^{MC} &= 765.98 \times 10^6, \\ N_{B\bar{B}} &= (771.58 \pm 10.56) \times 10^6. \end{aligned}$$

1474 Finally, we can determine the branching ratios based on the calculations in Eq.
1475 (7.15). The obtained values are shown in Table 7.6 and graphically shown in Fig-
1476 ure 7.11, along with the MC generated value and the current PDG world average.
1477 Both MC and measured determinations of the control decay branching ratio are
1478 in agreement with the expected and the world average values. One should note
1479 that the black error bars correspond to statistical uncertainty. Of all the systematic
1480 uncertainties, only the PID systematics are included in this results. Other contribu-
1481 tions of systematics are not included since this measurement is not the goal of our
1482 analysis.

7.4.3 Signal Fit to Data

Signal Yield

Finally, after making sure that the analysis procedure makes sense on the control MC, control data and signal MC sample, we can continue to perform the signal extraction process on the full Belle $\Upsilon(4S)$ data sample. Figure 7.12 shows the fit result in projections of ΔE and M_{BC} for both fit regions. The extracted signal yield on data as well as the yields of the remaining contributions are shown in Table 7.7. Values of all the constraints are shown in Table 7.8.

Figure 7.12: Signal fit result on real data. Left column shows the M_{BC} and the right column shows the ΔE distribution in the full fit window (top) and the signal window (bottom).

N_{10}	54 ± 7	N_{53}	21 ± 5
N_{11}	6 ± 2	N_{60}	69 ± 8
N_{20}	23 ± 5	N_{61}	94 ± 10
N_{21}	41 ± 6	N_{62}	63 ± 8
N_{22}	6 ± 2	N_{63}	35 ± 6

Table 7.8: Mean values and standard deviations of constraints after the fit.

In this fit setup, we perform a random smearing of the ΔE variable according to the Poisson distribution. The result is similar to a convolution with a Gaussian function, but the application is different in the sense that it returns a slightly different result after each fit. We perform 500 data fits in order to obtain the mean values of the signal yield and fit error. The averaged result is

$$\bar{N}_{sig} = 487 \pm 86, \quad \text{fit significance} = 5.9\sigma,$$

where the error represents the joint value of the statistical error as well as the systematic error of the Gaussian constraints used in the fit. This means that our initial fit is a good representation of the average fit result.

It is possible to estimate the contribution of the systematic uncertainty to the fit error above, which is found to be

$$\sigma_{stat} = 81, \quad \sigma_{sys}^{GC} = 29, \quad \delta_{sys}^{GC} = 6\%, \quad (7.16)$$

where GC stands for Gaussian constraint. Further details about systematic uncertainties can be found in chapter 8.

1498 Branching Ratio

Similarly as for the control decay, we are able to calculate the branching ratio of the signal decay via the formulas

$$\mathcal{B}_{\text{sig}}^{MC} = \frac{N_{\text{sig}}^{\text{MC}} \times \epsilon_{MC}}{2N_{B\bar{B}}^{MC}}, \quad (7.17)$$

$$\mathcal{B}_{\text{sig}} = \frac{N_{\text{sig}} \times \epsilon_{MC} \times \rho_{PID}}{2N_{B\bar{B}}}, \quad (7.18)$$

1499 where $N_{\text{sig}}^{\text{MC}}$ and N_{sig} are yields of the signal fit on MC and data, ϵ_{MC} is the MC
1500 efficiency of the signal sample, ρ_{PID} the PID correction factor, and $N_{B\bar{B}}^{MC}$ and $N_{B\bar{B}}$
1501 are the numbers of $B\bar{B}$ meson pairs on MC and data, respectively.

The signal efficiency was determined on the same signal MC sample as was used throughout the analysis. The full signal efficiency is determined to be

$$\epsilon_{MC} = (1.030 \pm 0.007) \times 10^{-2},$$

1502 where the efficiency error was calculated in the same manner as in section 7.4.2.
1503 The PID correction factors for signal and the numbers of $B\bar{B}$ meson pairs on MC
1504 and data are the same as in the case of control decay branching ration measurement

1505 Finally, we can determine the branching ratios based on the calculations in Eq.
1506 (7.18). The obtained values are shown in Table 7.9. We see that the measured value
1507 is twice as large as the MC value. The error in case of the MC result is statistical
1508 only, while the first and the second error in the data result are the statistical and
1509 the systematic errors, respectively.

1510 With the statistical significance of about 5.9σ this is the first observation of the
1511 charmless semileptonic decay $B^+ \rightarrow K^+ K^- \ell^+ \nu$. It indicates that the MC contribu-
1512 tion to our simulated samples is underestimated. This analysis has shown that the
1513 branching fraction of the decay seems considerable enough in order to affect results
1514 in precision physics in cases where they are ignored.

	$\mathcal{B}_{GEN} [\times 10^{-5}]$	$\mathcal{B}^{MC} [\times 10^{-5}]$	$\mathcal{B}^{\text{data}} [\times 10^{-5}]$
$\ell = e \text{ or } \mu$	1.57	1.60 ± 0.14	$3.09 \pm 0.52 \pm {}^{+0.66}_{-0.47}$

Table 7.9: Signal decay branching ratio results for MC and data.

1515 Signal Distribution in m_{KK}

1516 It is possible to take a deeper look in the signal decay distribution over the m_{KK}
1517 variable by performing the signal fit in windows over the m_{KK} distribution instead
1518 of a single fit over the whole region. This offers deeper insight into the real m_{KK}
1519 distribution and provides more detail about the reliability of our MC samples. Table
1520 7.10 shows the selected regions in m_{KK} , along with the corresponding signal yields
1521 on MC and data. The results are graphically shown in Figure 7.13. Figures for each
1522 m_{KK} window fit can be found in Appendix ??.

Chapter 8

Systematic Uncertainty

In this chapter, the systematic errors of the analysis are discussed. These uncertainties arise due to various reasons, some of them being the difference between real and simulated data, or due to the nature of the approaches taken in a specific analysis. Depending on their type, some uncertainties are generic and prepared beforehand in order to be used in all analyses, while others are analysis specific and possible sources need to be thought through thoroughly. All systematic uncertainties contributions which are cited in the final result in section 7.4.3 are summarized at the end of this chapter.

8.1 Contributions to Systematics

8.1.1 PID Efficiency Correction

The PID selection efficiency for the three charged particles in our signal decay needs to be corrected on MC due to various differences when comparing to data. The Belle PID group has prepared correction factors and systematics tables for PID efficiencies for all charged particles. In case of kaon ID and lepton ID, the tables are binned in experiment numbers, particle momentum and in $\cos\theta$ of the particle direction, where, for each bin, a ratio of efficiencies between MC and data is provided, as well as the systematic errors. Each particle's correction factor and error is shown in Table 8.1, as well as the corresponding entry for all 3 particles. The entries are shown for both signal and control region, where the differences are related to the kinematic variations between the signal and control modes.

The central values were obtained with a weighted average over all experiments, where 100% correlation for error calculation was assumed. A full correlation was also assumed when calculating the KK correction, as both K use the same PID information.

The final PID efficiency systematic error on the full MC sample is determined to be

$$\sigma_{\text{sys}}^{\text{PID}} = 10, \quad \delta_{\text{sys}}^{\text{PID}} = 2.0\%, \quad (8.1)$$

for the signal as well as the control decay.

PID correction and systematics	Control decay	Signal decay
Same sign K (w.r.t the B meson)	1.005 ± 0.009	1.007 ± 0.010
Opposite sign K (w.r.t the B meson)	1.004 ± 0.009	1.006 ± 0.009
e	0.977 ± 0.011	0.976 ± 0.011
μ	0.985 ± 0.009	0.980 ± 0.009
ℓ	0.981 ± 0.007	0.980 ± 0.007
KKe	0.986 ± 0.021	0.988 ± 0.022
$KK\mu$	0.994 ± 0.020	0.993 ± 0.021
$KK\ell$	0.990 ± 0.019	0.990 ± 0.020

Table 8.1: PID correction factors and systematic error for various charged particles and their combinations.

1552 8.1.2 Fit Bias and Binning Effects

Signal and background templates in our analysis are not perfectly distinct from one another and may potentially cause some over- or underestimation of the signal fit yield. In order to study this problem, we estimate the bias from the binning study performed in section 7.4.1 as well as the linearity test toy MC study in section 7.3.2. The two bias functions describe a bias in each direction and are approximated as

$$f_{\min}(x) = -7.25 - 1.12x - \sigma_{f_{\min}}(x), \quad (8.2)$$

$$\sigma_{f_{\min}}(x) = \sqrt{0.050x^2 - 0.175x + 0.410}, \quad (8.3)$$

$$f_{\max}(N_b) = 5.06 + \sigma_{f_{\max}}(N_b), \quad (8.4)$$

$$\sigma_{f_{\max}}(N_b) = \sqrt{0.004N_b^2 - 0.113N_b + 1.112} \quad (8.5)$$

1553 where x represents the signal yield fraction of the data fit and N_b represents the
1554 binning choice of the fit. Values of 1σ intervals have been added to the bias functions
1555 in order to be more conservative. The extracted signal yield on data with the fit
1556 setup of $N_b = 19$ bins was determined to be $N_{sig} = 487$, which leads to $x =$
1557 $N_{sig}/N_{sig}^{MC} = 487/250 \approx 2$. The bias interval is therefore

$$\sigma_{\text{sys}}^{\text{bias}} = {}^{+6}_{-10}, \quad \delta_{\text{sys}}^{\text{bias}} = {}^{+1.2\%}_{-2.1\%}. \quad (8.6)$$

1558 8.1.3 Gaussian Constraints

As mentioned in section 7.4.3, it is possible to estimate the size of the systematic error of the Gaussian constraints. By fixing the constraints to the nominal values, determined by the data fit, we obtain the pure statistical error, which can then be subtracted from the average fit error in order to determine the systematic uncertainty contribution due to using Gaussian constraints. For the fixed and non-fixed case we perform 500 fits and calculate with the mean values. The split errors are then

$$\bar{N}_{sig} = 487 \pm 86, \quad (8.7)$$

$$\bar{N}_{sig}^{\text{fix}} = 485 \pm 81, \quad (8.8)$$

$$\sigma_{\text{stat}} = 81, \quad \sigma_{\text{sys}}^{GC} = 29, \quad \delta_{\text{sys}}^{GC} = 6.0\%, \quad (8.9)$$

1559 where GC stands for Gaussian constraint. We see that the constrained channels are
1560 very well defined and introduce little to none additional uncertainty.

8.1.4 Fit Template Smearing and Offset

The smearing and offset of the ΔE variable was discussed in section 7.1.1, where we have estimated the central value of the parameters as well as their range in the 1σ confidence level. We have to perform a study of the effects of different smearing and offset parameter values on the final value of the signal yield. From section 7.1.1, the parameter values are

- Smearing: 40^{+15}_{-17} MeV,
- Offset: $6^{+4.6}_{-6}$ MeV.

Since the two parameters are largely uncorrelated, we are able to perform the study in the form of signal fits with four different combinations of parameters in the given range. For each parameter setting 500 fits are performed and the following results are obtained

- Set: [smearing, offset]: [23 MeV, 6 MeV], Result: $\bar{N}_{sig} = 446$,
- Set: [smearing, offset]: [55 MeV, 6 MeV], Result: $\bar{N}_{sig} = 538$,
- Set: [smearing, offset]: [40 MeV, 0 MeV], Result: $\bar{N}_{sig} = 547$,
- Set: [smearing, offset]: [40 MeV, 12.6 MeV], Result: $\bar{N}_{sig} = 439$,

which results in the following estimate of systematic uncertainties for smearing and offset parameters

$$\sigma_{sys}^{sm.} = {}^{+53}_{-39}, \quad \delta_{sys}^{sm.} = {}^{+10.9\%}_{-8.1\%}, \quad (8.10)$$

$$\sigma_{sys}^{off.} = {}^{+62}_{-46}, \quad \delta_{sys}^{off.} = {}^{+12.8\%}_{-9.5\%}. \quad (8.11)$$

8.1.5 Effects of a Finite MC sample

The shape of signal and backgrounds templates in our analysis is fixed and only their normalization is considered as a floating parameter in the fit. Due to the finite size of the MC sample, the template shape introduces an additional source of uncertainty, as it may differ if produced in a separate, equal-sized MC sample. Since the bins in these 2D histogram templates are statistically independent, we take the content of each bin and vary the value according to the Poisson distribution. This procedure is repeated 500 times and the width of the fit yield distribution is taken as the uncertainty estimate. The resulting finite MC sample contribution of the systematic uncertainty is

$$\sigma_{sys}^{MC} = 27, \quad \delta_{sys}^{MC} = 5.5\%. \quad (8.12)$$

8.1.6 MVA Selection Efficiencies

Control sample fits allow us to check the behavior of optimized MVA cuts on MC as well as data and see if any of the MVA steps introduce a possible disagreement between the two. We compare control yields, their ratios, and ratios of cut efficiencies (double ratios). The following cut scenarios are studied

- 1592 (a) final selection before any MVA step,
- 1593 (b) (a) + $BDT_{q\bar{q}}$ cut,
- 1594 (c) (a) + $uBDT_{B\bar{B}}$ cut,
- 1595 (d) (a) + $BDT_{q\bar{q}} + uBDT_{B\bar{B}}$ cut (final selection).

1596 The results for control fit yields, their ratios, and double ratios are shown in Figure
 1597 8.1. The plot shows that the yield ratios and cut efficiency ratios are consistent with
 1598 1. This means that data and MC are in agreement before as well as after applying
 1599 the final selection cuts. This is an important check since the behavior of our analysis
 1600 on the control sample suggests that the final selection is not over-optimized to signal
 1601 MC.

1602 We estimate the systematic error due to the MVA selection steps as the standard
 1603 deviation of double ratio entries around the nominal value for each step in the
 1604 MVA selection, except for the final two values for e and μ modes, since we are
 1605 performing the inclusive lepton measurement. The systematic error estimate for
 1606 this contribution is

$$\sigma_{\text{sys.}}^{\text{MVA}} = 5, \quad \sigma_{\text{sys.}}^{\text{MVA}} = 1.0\%. \quad (8.13)$$

Figure 8.1: Fit yields, their ratios and ratios of cut efficiencies (double ratios) for the control sample fits to data and MC.

8.1.7 Model Uncertainty Effects

The signal decay model used in the generation step was ISGW2 [19], which is known to result in unrealistic predictions and poor agreement with data, so it is not the most precise model for our signal MC sample. Due to this model unreliability, our analysis has been set up as model-independent as possible via means of not using variables, which exhibit model dependence. Such variables are i.e. squared momentum transfer to the lepton pair (q^2), the invariant mass of the two kaon daughters (m_{KK}) or decay angle between any two charged particles in the final state. In order to test the effects of model dependency on our final result, we prepare two additional signal MC samples, produced with two extreme scenarios of decay model choice. In the first scenario we generate the signal MC sample with a generic phase-space decay mode PHSP [6], which results in continuum-like distributions of q^2 and m_{KK} . In the other scenario, only resonant-like contributions of m_{KK} are used. These two scenarios act as extreme cases of decay model choice and present a

reasonable measure of the model uncertainty. Figure 8.2 shows the generated m_{KK} and q^2 distributions of the three mentioned decay models as well as distributions of ΔE and M_{BC} after the final selection. Figures show a good agreement of ΔE and M_{BC} , even if the signal model is very different. This proves that our analysis is model-independent to a satisfactory extent.

The systematic uncertainty due to the model dependence is estimated via using the different signal MC samples as signal templates in the fit. We perform 500 fits for each case. The differences between mean values of fit yields serve as an estimate of the model uncertainty.

Figure 8.2: m_{KK} (top left), q^2 (top right), ΔE (bottom left) and M_{BC} (bottom right) for three different signal MC datasets with the standard ISGW2 decay model and two extreme cases of decay models, phase-space (PHSP) and resonant (RES) modes.

The resulting average signal yields for the three model choices are

$$\bar{N}_{sig} = 487, \quad (8.14)$$

$$\bar{N}_{sig}^{\text{PHSP}} = 532, \quad (8.15)$$

$$\bar{N}_{sig}^{\text{res.}} = 490. \quad (8.16)$$

Any kind of different signal model will likely result in a worse resolution of the 2D distribution in ΔE and M_{BC} , which results in a larger yield, so the increase of the yields obtained with different models is expected. The systematic uncertainty due to model dependence is therefore estimated to be asymmetric with a value of

$$\sigma_{\text{sys}}^{\text{mod.}} = {}^{+47}_{-0}, \quad \delta_{\text{sys}}^{\text{mod.}} = {}^{+9.7\%}_{-0.0\%}. \quad (8.17)$$

8.2 Summary of Systematics

The summary of all systematic uncertainties is shown in Table 8.2. The full estimate of the systematic uncertainty is summed up in quadrature and applied to the result in section 7.4.3.

Source	σ	δ [%]
PID	10	2
Fit Bias	${}^{+6}_{-10}$	${}^{+1.2}_{-2.1}$
Gaussian Constraints	29	6.0
Template Smearing	${}^{+53}_{-39}$	${}^{+10.9}_{-8.1}$
Template Offset	${}^{+62}_{-46}$	${}^{+12.8}_{-9.5}$
Finite MC Effects	27	5.5
MVA Selection	5	1.0
Model Dependence	${}^{+47}_{-0}$	${}^{+9.7}_{-0.0}$
Total	${}^{+103}_{-73}$	${}^{+21.3}_{-15.1}$

1727 10.3 Uniformity Boosted $B\bar{B}$ Suppression 1728 Training

1729 10.3.1 Hyper-parameter Optimization

1730 Hyper-parameters were not optimized due to the large CPU time consumption of
1731 the algorithm. The following set up of the hyper-parameters was chosen

- 1732 • nTrees: 300
- 1733 • nLevels: 4

10.3.2 Results

Figure 10.9: Efficiency (\mathcal{E}) and purity (\mathcal{P}) of the uniformity boosted MVA classifier output for $B\bar{B}$ background suppression training on the train (solid) and test (dashed) samples.

Figure 10.10: ROC curves of the uniformity boosted MVA classifier output for $B\bar{B}$ background suppression training on the train (solid) and test (dashed) samples.
